The Rôle of Specific Carbohydrates in Pneumococcus Infection and Immunity*†

By OSWALD T. AVERY, M D, *New York City*

MR President; Fellows of the American College of Physicians.

I count it a great privilege to be able on this occasion to express personally my deep sense of appreciation of the distinguished honor conferred upon me by the American College of Physicians. In awarding me the John Phillips Memorial Prize I feel that you have been far too generous in your appraisal of my share in the work for which this distinction is granted. I am conscious that whatever merit may accrue to the studies in which it has been my privilege to participate is due in great part to the happy auspices under which the work is carried on, and in large measure to the devoted and hearty cooperation of my associates. To them, I am indebted for an association that to me has been a source of genuine pleasure and great helpfulness, and to them I am happy on this occasion to acknowledge my obligation.

*From the Hospital of the Rockefeller Institute, New York City

†Delivered at the San Francisco Meeting of the American College of Physicians, April 6, 1932, at the presentation of the John Phillips Memorial Prize

I find great satisfaction in the thought that in making this award, you are symbolizing in a far larger sense than the mere personal recognition implies, your faith in the spirit of research and the principles of practice expressed by Osler in these words: "To wrest from nature the secrets which have perplexed philosophers in all ages, to track to their sources the causes of disease, to correlate the vast stores of knowledge, that they may be quickly available for the prevention and cure of disease—these are our ambitions. To carefully observe the phenomena of life in all its phases normal and perverted, to make perfect the most difficult of all the arts, the art of observation, to call to aid the science of experimentation, to cultivate the reasoning faculty, so as to be able to know the true from the false—these are our methods. To prevent disease, to relieve suffering and to heal the sick—this is our work."

To all who cherish these ambitions, cultivate these methods, and delight in this work, the example of him in whose memory this award has been established will remain a continuing source of inspiration.

Permit me once more to assure you

of my grateful appreciation of the signal honor of being enrolled as one of the recipients of the John Phillips Memorial Prize

AN important advance in the study of infectious diseases came with the knowledge that bacteria, though simple in form and structure, exhibit differences in biological specificity as sharply defined as are those characteristic of the more complex forms of life. The study of the immunological specificity of microorganisms is not only necessary in the elucidation of the biological relationships existing between varieties of the same species of bacterium but is essential to the working out of epidemiological problems and to the development of methods useful in the control of infectious diseases by specific therapeutic and prophylactic measures.

Leaving out of consideration the promising but difficult field of chemotherapy, the problems of specific cure and prevention of infection lie in the attempt to interpret and imitate by artificial procedures certain protective processes of nature which constitute that which we call immunity. In order to imitate successfully the natural processes involved in spontaneous recovery from disease, it is necessary to know the nature of the specific reactions between the infecting agent and the body tissues of the host. The specificity of these biological processes is advantageously studied by means of the so-called immunity reactions. These serve as a measure of the capacity of the animal organism to produce protective substances, and they afford a means of studying the interaction be-

tween these specific antibodies and the infectious microorganism when both are brought together in the animal body or in the test tube.

Investigations on the specificity of these reactions have added much to our knowledge of the many and diverse problems of infection. The study, however, is one of varying complexity, the methods suitable in one instance fail utterly when applied to another type of infection. While the mechanism of the interaction between host and parasite has to a certain extent been exposed through the brilliant discoveries of Metchnikoff, Ehrlich, Behring, Bordet and others, the immediate problem lies in reconstructing for each microbe a more precise knowledge of the biological properties peculiar to it and the specific reactions which the body develops against it. One approach to this problem is the attempt to relate specific differences in biological behavior to fundamental differences in the function and chemical composition of the component parts of the bacterial cell and to determine the character of the tissue responses to these separate constituents. The total immune response of the host comprises not alone a reaction to the parasite as a whole, but, in addition, the specific and individualized responses to the chemically distinct and immunologically specific bacterial constituents.

For the past several years under the direction of Dr. Rufus Cole a number of us on the staff of the Hospital of the Rockefeller Institute have been seeking to acquire a more intimate knowledge of the relation between the immuno-chemistry and the biological activities of pneumococcus, the most

frequent and one of the most fatal of the microbic incitants of pneumonia in man

On this occasion I shall review briefly one phase of the studies, namely, the rôle of specific carbohydrates in pneumococcus infection and immunity. Because of the limited time at my disposal, I shall of necessity be obliged to omit reference to the valuable contributions of that large group of other investigators who, both in this country and abroad, have added so much to our knowledge of the problems of pneumococcus pneumonia.

You are already familiar with the renewed impetus that was given to the study of pneumonia by the working out of the biological classification of pneumococci which made possible the recognition of sharply defined and specific types within this previously confused species of microorganisms. You will recall that by the application of this method it has been possible to determine the frequency of occurrence of these specific types in pneumonia, and to recognize differences in the severity and mortality of the infections they produce, that a study of the presence of pneumococci in the mouth secretion of healthy individuals proved the dissemination of the disease-producing types by healthy carriers and convalescents and suggested a new interpretation of the epidemiology of the disease, and finally that the knowledge of type-specificity among pneumococci provides the only rational basis for the possible development of specific therapy by immune serum, which in the treatment of type I infections, at least, has proved of distinct value.

Pneumococcus is a unicellular micro-

organism which under well-defined conditions of growth is surrounded by an envelope of material known as the cell capsule. This capsular layer is particularly well developed in the case of pneumococci capable of growing and multiplying in the animal body. During growth these encapsulated cells elaborate in the medium of their environment a diffusible substance which in soluble form retains the type-specificity of the bacterial cells from which it is derived. This soluble specific substance is found not only in the filtrates of young cultures but also in the body fluids of animals experimentally infected, and in the blood and urine of patients during the course of pneumococcus pneumonia. The function of elaborating this specific material is most highly developed in the most virulent organisms. There are grounds for the belief that the capsule of these virulent cells is composed largely of this soluble specific substance. Thus, there is disposed peripherally about the cell an outer layer of capsular substance which reacts specifically with the serum of immune animals. The reaction is remarkably specific, occurring only when the anti-serum and the reacting substance are both of the same specific type. These immunological reactions form the basis of the original classification and were worked out before there was any knowledge of the chemical nature of the substances upon which type-specificity depends. The actual isolation of these specific substances in purified form, the determination of their chemical constitution and their relationship to the immunological properties of the

cell as a whole are problems to which I shall direct attention.

The type-specific capsular substances of pneumococcus, first chemically isolated by Dr. Heidelberger, have been found in each instance to belong to the class of sugar-like substances, namely, the carbohydrates. No matter from what type of pneumococcus these specific substances are recovered they all possess in common the chemical properties of complex sugars—the polysaccharides. But, interestingly enough, the capsular polysaccharide derived from each specific type of organism is chemically distinct, each possessing unique chemical properties which serve to differentiate it sharply from the others. Moreover, solutions of these capsular polysaccharides in chemically purified form, exhibit immunologically the same specificity as do the bacteria of which they originally formed a part. Some idea of how remarkably reactive these sugars are may be judged from the fact that, by the use of an appropriate serum, their presence may be detected in dilutions as high as 1:5,000,000.

Dr. Heidelberger and Dr. Goebel, studying the chemistry of the capsular polysaccharides, have shown that these substances are unusual compounds of simple sugars and uronic acids. Although possessing many properties in common, they exhibit characteristic differences in the degree to which they rotate the plane of polarized light and in their acid equivalent number. For example, of the specific substances of the first three types of pneumococcus, the type I polysaccharide differs sharply from the other two in containing nitrogen as an integral part of the

molecule, and in possessing basic as well as acidic properties; on the other hand the type II polysaccharide is a dextrorotatory weak acid and the type III a levorotatory strong acid, neither of which contains any nitrogen in the molecule. The fact that the particular constituent determining type-specificity is chemically a carbohydrate is the more striking since immunity reactions have hitherto been considered exclusively the function of proteins. Of equal importance is the fact that this selective specificity is in each instance determined by the chemical constitution of the particular polysaccharide in the capsule and that the presence of this morphological structure conditions both the invasiveness of the parasite and the immune response of the host.

The fact that polysaccharides elaborated by bacteria growing in the focus of disease may be found in the blood and urine, unchanged in specificity, indicates that the body possesses no enzymes capable of breaking them down into simpler sugars. There is no evidence that these complex bacterial sugars *as such* are directly responsible for the intoxication accompanying the infection. So far as known they are not primarily toxic, at least not in the sense of true bacterial toxins. There are facts, however, which indicate that indirectly at least they may have a harmful effect upon the natural processes of recovery. Because of their specific capacity to bind antibodies, they tend to neutralize the immune substances in the blood and thus prevent the protective antibodies from reaching the infected areas. Moreover, the capsular polysaccharides are known to exert an inhibiting action on phagocytosis, one

of the most important cellular defenses of the body against pneumococcus infection

Theoretically, at least, there is no apparent reason why these complex sugars as isolated substances should not by themselves be capable of stimulating the formation of antibodies in the animal body. Assuming that they are of sufficient molecular size, they possess in complexity of structure and colloidal behavior certain properties generally considered essential to the antigenicity of proteins. Indeed, Francis and Tillett have found that in the present state of purity the capsular polysaccharides are capable of inciting antibody production when injected in minute amounts into the skin of convalescents and normal individuals. However, with few exceptions all attempts to evoke any immune response in animals with the highly purified polysaccharides alone have been uniformly unsuccessful. On the other hand, the more these carbohydrates are chemically purified, the more reactive they become in the specific serum of immune animals. Under these conditions it appears that, removed from the bacterial cells, the capsular polysaccharides still retain unimpaired the property of binding with antibodies, although in this form they become quantitatively less active in stimulating antibody production in animals. In this respect they may rightly be included in the group of immunologically important substances which Landsteiner has called haptens,—substances which have lost more or less completely their antibody-stimulating function without impairment of the property of specifically combining with antibodies.

The elaboration of the capsular polysaccharide is an important function of the cell. When this function is suppressed or inhibited, as it may be under certain experimental conditions of growth, the capsule is no longer formed. As a result the organisms lose their type-specificity and exhibit only the common, undifferentiated characters of the species. On the basis of colony differentiation these degraded organisms are spoken of as the "R" or rough forms, and the original encapsulated types are referred to as the smooth or "S" organisms. The unencapsulated R forms of pneumococci, irrespective of their type derivation, are no longer capable of invading the animal body, they have lost their virulence, and are readily taken up and destroyed by the phagocytes of the host, immunologically they exhibit only the species-specificity common to all the degraded R forms of pneumococcus. This transformation resulting in a loss of specific characters may occur in the animal body as well as in the test tube. However, these degraded, avirulent variants do not necessarily remain the harmless saprophytes they were originally thought to be, since it is now known that under suitable conditions they may regain all the specific characteristics that distinguished the original parasitic type from which they came.

Of even greater biological interest is the phenomenon of the inter-convertibility of the specific types of pneumococcus. Griffith of London first showed experimentally by a special technique in mice that R forms derived from one specific type of pneumococcus may be caused to acquire the characteristics of

another specific type. This important fact has been confirmed by a number of investigators. In addition, Dawson and Sia by special cultural methods, have found that the actual change from one specific type of pneumococcus to another may be brought about in the test tube outside the animal body.

The experimental evidence now available seems to indicate that any R strain of pneumococcus has potentially the function of elaborating any one of the specific capsular polysaccharides;—the particular one being determined by a particular stimulus of a specific nature. Aloway has recently found that this potential function latent in the living R cells may be specifically activated by the addition to an appropriate medium of a bacterial extract prepared from a given specific type of pneumococcus. Under these conditions, the R forms irrespective of their type derivation again elaborate a capsular material identical in specificity with that of the type of pneumococcus from which the extract was prepared.

There is at present no certain proof that transformations of this kind ever occur spontaneously in nature. Nor is there as yet any epidemiological or clinical evidence that this form of reversible adaption is a factor in the origin of human infection. However, the experimental evidence leaves no doubt that the non-invasive, non-encapsulated R cells under favorable circumstances are potentially capable of again developing into highly virulent organisms and that the acquisition of virulence is invariably associated with the restoration of the function of elaborating the specific capsular carbo-

hydrates. Indeed, it is most significant that no matter whether one considers pneumococcus from the viewpoint of virulence, antigenicity, or its capacity to undergo variation, the single determining factor associated with all these characters is the function of synthesizing the specific capsular polysaccharides. Scarcely less important is the fact that the immunological specificity of each of the specific types of pneumococcus depends upon the chemical individuality of the particular carbohydrate in the cell capsule.

As chemical substances, separate and apart from the bacterial cells, these carbohydrates have been found to incite specific reactions in the tissues of sensitized animals and in the skin of patients convalescent from pneumococcus pneumonia. Guinea pigs passively sensitized with the precipitating serum of an immune rabbit suffer violent anaphylactic shock and die within three to four minutes following the intravenous injection of as little as 0.55 mg. of the homologous polysaccharide. The anaphylactic reactions are strictly type-specific. There is now ample evidence to support the view that protein-free, even nitrogen-free, carbohydrates may induce acute anaphylaxis in specifically sensitized animals.

Tillett and Francis have found that the injection of 0.01 mg. of specific polysaccharide into the skin of patients recovering from pneumococcus pneumonia may evoke an immediate local reaction in the form of a wheal surrounded by a zone of erythema. The cutaneous reactions develop rapidly within fifteen minutes and subside completely in from one to two hours; they are elicited only by the specific

polysaccharide derived from the same type of pneumococcus as that causing the infection in the patient. The capacity of the skin to react to the specific bacterial sugar is intimately associated with recovery and closely parallels the occurrence of type-specific antibodies in the patient's serum. The results indicate that this specific skin test has prognostic significance and may become of value in determining the therapeutic dosage of antipneumococcus serum.

Studies on "synthetic antigens" prepared by chemically combining derivatives of glucose and galactose with proteins have shown that even these simple sugars exert a determining influence on the immunological specificity of compounds of which they form a part. The newly acquired specificity of these artificially conjugated sugar-proteins is in each instance determined by the chemical structure of the carbohydrate irrespective of the protein to which it is attached. It is especially significant in the case of glucose and galactose that the two sugar derivatives differ from each other only in the spatial arrangement of the hydrogen and hydroxyl groups on a single carbon atom. It is a remarkable fact that the mere rotation of this carbon atom through an angle of 180° suffices to change completely the antigenic specificity of two substances otherwise chemically identical. In the case of these artificially prepared sugar-proteins, the two isomeric sugar derivatives can be selectively differentiated one from the other by serological methods. These observations on the immuno-chemistry of carbohydrates confirm the original studies of Land-

steiner on the specificity of azo-proteins and furnish additional evidence of the general dependence of immunological specificity upon the chemical constitution of the reactive substances. It is evident, therefore, that simple sugars, which by themselves are non-antigenic, may, when coupled to a protein, specifically determine the immune response of treated animals, and that the antibodies thus engendered reflect the orienting influence of the sugar radical on the specificity of the antigen as a whole.

From these results we were led to test the possibility of "synthesizing" an artificial bacterial antigen. For this purpose the capsular polysaccharide of type III pneumococcus was chosen, since it contains no nitrogen and in its present state of purity may be regarded as a definite chemical entity. Moreover, if results were obtained with this particular polysaccharide they would be the more significant, since the free substance by itself has never been found to elicit any immune response in rabbits and even the original bacterial cells from which it is derived fail in a majority of instances to incite specific antibodies in these animals. From a chemical point of view, the difficulty lay in synthesizing the appropriate derivative of this complex sugar. It must be one capable of being coupled to protein and one in which the chemo-specific groups of the polysaccharide are not masked by the chemical procedures. Dr. Goebel succeeded in synthesizing the amino-benzyl-ether of the type III polysaccharide and in coupling the diazonium derivative with a foreign protein, namely, the globulin from horse serum.

This soluble antigen therefore has in common with type III pneumococcus only the specific capsular polysaccharide. Rabbits injected with this artificial antigen uniformly developed in their serum type-specific antibodies. The antiserum thus produced not only precipitates the original polysaccharide but agglutinates living cultures of type III pneumococcus and protects animals against infection with virulent organisms of the homologous type.

Knowledge of the chemical nature and significance of the capsular polysaccharides in pneumococcus infection and immunity led us to search for enzymes capable of decomposing these specific carbohydrates. A number of enzymes of animal and plant origin as well as cultures of various bacteria, yeasts, molds and soil actinomycetes, many of which were known to decompose cellulose and other complex carbohydrates, were tested without success. My associate, Dr. Dubos, isolated from peat soil a bacillus which possesses an enzyme that acts specifically on the capsular polysaccharide of type III pneumococcus. From these bacilli the active enzyme has been extracted in soluble form. By technical procedures, active preparations of the enzyme have been purified and concentrated without appreciable loss in potency.

In view of the marked differences in the chemical composition of the various capsular polysaccharides, it is not surprising to find that the enzyme decomposes only the type III substance and has no effect upon any of the other bacterial sugars thus far tested. In this respect, the selective action of the enzyme is as specific as in the immune

reaction between the type III polysaccharide and its homologous antibody. The polysaccharide acted upon by the enzyme loses its serological specificity and is no longer precipitable by type III antipneumococcus serum. This enzyme not only acts on the chemically isolated sugar, but it specifically decomposes this substance in the native form in which it exists in the capsules of the living cells. When a sterile solution of active enzyme is added to a growing culture of type III pneumococci, the organisms lose their specific agglutinability and the soluble capsular polysaccharide is serologically no longer demonstrable in the culture fluid. Under these conditions, the enzyme decomposes the capsular substance as rapidly as it is formed without impairing the viability of the de-capsulated organisms.

The action of the enzyme does not result in a loss of the function of elaborating the capsular substance, since pneumococci so treated promptly regain their capsules when transferred to an enzyme-free medium. The active enzyme, therefore, represents a specific agent which by itself is neither bactericidal nor bacteriolytic but which, by decomposing the capsular structure, completely alters the biological behavior of the bacterial cell.

In view of these findings, experiments were carried out to determine whether the enzyme would favorably influence the course of experimental infection in mice with type III pneumococcus. It was found that a single injection of an active preparation of enzyme protected mice against infection with a million times the number of virulent organisms invariably fatal

in the untreated animals. The protective action of the enzyme is type-specific, just as in the test tube it decomposes only the type III polysaccharide, so in the animal body it is effective only against infection with type III pneumococcus.

Experimental evidence indicates that in mice the enzyme also has a curative action when administered in the course of an infection already well established at the time of treatment. The administration of the specific agent as late as eighteen hours after the onset of infection has brought about the recovery of mice infected with multiple lethal amounts of a virulent culture of type III pneumococcus. Experiments carried out in collaboration with Dr Goodner and Dr Dubos have shown that the enzyme also has a marked curative action in the disease brought about by infecting rabbits intradermally with a highly virulent strain of type III pneumococcus. The experimental disease is characterized by the rapid development at the site of inoculation of an intense inflammatory lesion with spreading edema, marked cellular infiltration and hemorrhagic necrosis, accompanied by fever and the early invasion of the blood stream with increasing numbers of pneumococci. The infection ordinarily terminates fatally within three to four days in 95 per cent of untreated rabbits. Following the intravenous injection of an adequate amount of active enzyme the bacteremia promptly disappears, the

local lesion, freed of bacteria, undergoes the natural processes of healing, and recovery occurs in 95 per cent of the animals so treated.

The experimental results support the view that the primary action of the enzyme lies in its capacity to decompose the capsular polysaccharide of the invading pneumococci. The process of decapsulation brought about by the direct action of the enzyme strips the bacteria of their capsular defense and thereby exposes their naked and unprotected bodies to direct attack by the phagocytes of the host. Thus phagocytosis, ineffective against the encapsulated forms, now becomes the important mechanism in the final destruction of organisms from which the capsular substance has been removed by the action of the enzyme.

In this sense, the enzyme may be said to initiate a protective reaction, the successful issue of which depends upon the effective phagocytic response of the host. For these reasons, it at once becomes apparent that the curative action of the enzyme is subject to the limitations imposed by the variations that occur in the cellular defense of the infected animal.

These studies suggest that the capsule—long recognized as a defense mechanism on the part of virulent bacteria—is a decisive factor in determining the fate of pneumococci in the animal body and that this structure is vulnerable to attack by agents other than specific antibodies.

Presentation of the John Phillips Memorial Prize*

By S. MARK WHITE, M. D.
President of the American College of Physicians

DR. Avery, Fellows of the American College of Physicians, Associates and Guests

John Phillips was born in Welland, Ontario, February 18, 1879. With a personality marked by simplicity, directness, poise and a remarkable sense of relative values, he came in the fifty years of his life to a high place in medicine in this country. Work was his philosophy of life. He exemplified this, called by Osler the Master Word. His intimate friends tell us he appeared not to know how to play. His contributions to medicine and its literature were many, and were scholarly and sound. Elected to the Board of Regents of the American College of Physicians in 1923, he was active in its affairs in many and important ways. He arranged the programs for the Annual Sessions in Cleveland in 1927.

Valuable as we who knew him held his life to be, he held it as naught if it was needed in the succor of others. When disaster visited the Cleveland Clinic in 1929, he, Chief of Medicine, without thought of self, labored to save its victims. Giving his life on May 15, 1929, he left us a glorious example. The college has founded this annual prize to perpetuate his memory.

The purpose of this prize is to encourage work adding to our knowledge in Internal Medicine, this including not only clinical science but in addition all those subjects which have a direct bearing upon its advancement.

When in one of the Hippocratic writings, "The Law", we read, "There are in effect two things, to know and to believe one knows, to know is science; to believe one knows is ignorance", we are on the threshold of the conception of medicine as an art based on accurate observation, and as a part of the science of man. When many centuries later we follow William Harvey and René Descartes in "la nouvelle methode" of experimental science, we are preparing to wrest from nature some of her profoundest secrets. Induction, intuition, and deduction, served by the sometimes slow, painstaking methods of trial and error, lead us to an understanding of nature never suspected by the ancients. But here again we glimpse what they so plainly saw, "Life is short and the Art is long". Fifty years have passed since Robert Koch discovered the bacillus of tuberculosis. The conquest of the disease, though well under way, is not yet complete. In the meantime, yellow fever has been eliminated from the

*April 6, 1932

civilized world, through the efforts of a devoted band of scientists with its martyrs, even though the causative organism may be yet in doubt. Illustrations need not be multiplied.

Fifty years have passed since Friedlander found that capsulated cocci were present constantly in the exudate of pneumonia, and two years after that, Fraenkel demonstrated the causative relation of the pneumococcus to the disease. Our conquest of pneumonia has scarcely begun. We are beginning to see it as through a glass, darkly, however. All honor then to the men, who step by step, are treading the paths that will eventually lead to the hiding place of the pneumococcus, and who by the processes of science, though they be slow and painstaking, are discovering how to strip it of its protective covering.

The committee having in charge the award, in seeking a candidate, selected an advisory group of sixteen members of the College, each prominent in some certain aspect or field of medicine. The suggestions made by each of these, and by the members of the committee, were

listed and then sent out to the two groups, with the request that each man would indicate his first, second and third choice from amongst that list. Twenty-five of the votes went to Dr Avery.

The committee, therefore, through its chairman, Dr James H. Means, recommends the award, "To Dr O. T. Avery for the series of studies upon the pneumococcus in which he has played a leading rôle, beginning with the discovery of the type specific soluble capsular polysaccharides and culminating in the discovery of a bacterium producing an enzyme which splits the polysaccharides of type III pneumococcus in vitro, thus rendering it susceptible to phagocytosis and thereby protecting the animals which are infected with it." Dr Avery, you are the first recipient of this annual award. As evidence of appreciation of your industry, your devotion to Science and your scholarly attainments we present you, in the sum of \$1500.00, with this, the John Phillips Memorial Prize of the American College of Physicians.

Physical and Physiological Aspects of Arteriosclerosis and Hypertension*

By CARL J. WIGGERS, M.D., F.A.C.P.,
Cleveland, Ohio

INTRODUCTION

THE subjects of arteriosclerosis and hypertension have been extensively studied and even more extensively discussed by the clinician, pathologist, therapist and experimentalist, each naturally, according to his own point of view. But results of physical and physiological investigations have been more or less entombed in library stack-rooms, at least to my knowledge they have not been reviewed in such a form as to make the facts easily available.

My own venture in attempting to review a topic in which so many gaps still exist is actuated by our need for survey of the known physical and physiological consequences of arterial disease. Such an adventure is of triple value: it places the essential known facts in orderly array, it reveals the gaps and questionable evidence and supplies a working basis from which new physiological investigations may proceed. Indeed, such a systematic

survey and critical evaluation of existing theory and fact forms a natural prelude to an interpretation of those experiments which Nature chooses to make on animals and man, and which are designated by the term, Disease.

PHYSIOLOGICAL FACTORS IN HYPERTENSION

Two primary vascular changes may be concerned in hypertension, viz., (a) alterations in the elastic properties of the large arteries which serve as physical buffers to the capillary flow and (b) changes in the lumen and resistance of the smaller arterioles which act in the capacity of stopcocks regulating the outflow from the arterial tree. In addition, secondary changes in the action of the heart supervene and complicate the dynamic picture. When, as in this instance, the heart and circulation are affected by a number of different factors it becomes confusing, if not quite hopeless, to evaluate the share that each element contributes. In such instances, physiologists frequently adopt the expedient of studying the changes in the heart and circulation when only a single factor alters at a time. We shall utilize this method in analyzing the hypertension problem.

*From the Department of Physiology, Western Reserve University School of Medicine, Cleveland, Ohio. Read before the American College of Physicians, San Francisco, April 6, 1932.

THE EVALUATION OF ARTERIAL ELASTICITY

Studies on Excised Vessels The elasticity of tubular structures such as arteries is usually determined by measuring the increase in cubic contents when the internal pressure is raised a definite amount. The ratio, pressure increase to volume increase ($\frac{dp}{dV} V$), is designated the *volume elasticity coefficient* (E_v). Obviously, such a coefficient increases inversely as elasticity and directly as rigidity.

Physical tests have demonstrated that arteries are not equally distensible at all internal pressures, on the contrary, their distensibility decreases progressively as internal pressure is raised. A curve in which pressures as abscissae are plotted against volumes as ordinates therefore assumes a hyperbolic form, convex to the abscissae (figure 1, A). When medium sized arteries, such as the carotid, brachial or radial are studied, it is often found that the reactions differ both quantitatively and

qualitatively in repeated tests. Two other forms of curves, illustrated by B and C in figure 1, are often obtained. Each of these has, indeed, been advocated as representing the true volume-elasticity curve of arteries. MacWilliam (1902) concluded that these variations are due, in large part at least, to variable degrees of muscular contraction. According to his studies, moderate muscular contraction hinders stretching at lower internal pressures only, hence the elasticity coefficient follows an S-shaped curve (B). If, however, the vessels are firmly contracted, the muscular force opposes distention at all ranges of internal pressures, hence a straight line or concave elasticity curve (C) is the result. It is obvious that the excursion of peripheral arteries such as the radial and perhaps the brachial may not be governed solely by internal pulse pressure variations but by the degree of muscular contraction as well.

When an artery becomes less elastic through sclerotic processes or chemical

FIG 1 Volume elasticity curves of medium sized arteries. A, relaxed vessels, B, moderately contracted vessels, C, strongly contracted vessels

treatment, its distensibility under equivalent pressures is not merely decreased but the form of the extensibility curve also changes. Obviously some other factor, that may be spoken of as the elastic "personality" of the vessel, is altered.

Frank (1927) designated this by q in the equation $E = E_0 + q\sigma^2$, in which E_0 denotes the residual elastic resistance of unstretched vessels and σ the specific tension per unit cross-section area

After mathematical treatment of the problem (1920, 1928) Frank (1927), in association with Mays and Hochrein, reported experiments on rings of aortas obtained post-mortem from individuals of different ages. Such central vessels have the advantage of giving constant responses because the experiments are not complicated by the effects of muscular contraction. These data have been plotted, using E values as ordi-

nates and σ values as abscissae (figure 2). A glance shows that in young persons arterial rigidity (E) increases very little at lower tensions but trends rapidly upward at higher tensions (σ). In case of aortas from older subjects, on the contrary, the lines begin to curve upward at progressively lower tensions and, moreover, rise with a steeper gradient until in very old age they become almost straight lines from the start. Such curves indicate that while the residual elasticity of arteries (E_0) does not alter with age, their extensibility decreases rapidly with increasing tensions and more especially at lower tensions. Graphs such as these give a qualitative and objective picture of the changes concerned in ageing of the arteries. Since the co-ordinates of each curve can be expressed mathematically as a rational function of their parameter—i.e., q in Frank's formula—it is possible to cal-

FIG 2 Curves showing the elastic coefficients (E) of aortas at different specific tensions, (σ) at ages directly indicated on the chart. E and σ , expressed in 10^6 dynes, a unit which corresponds approximately to pressure exerted by an atmosphere per cm^2 (after Frank)

culate values for q^* and to express the age characteristics in a quantitative fashion, as in figure 3. A consideration of such graphs led Frank to the conclusion that while the residual elasticity (E_0) scarcely alters with age extremes (5-87 years) the parameter q increases more than sixfold

ing to the classical formula of Moens ($V \approx K\sqrt{g \frac{Ea}{sd}}$) the pulse wave velocity (V) varies directly as the square root of gravity (g), the elasticity coefficient (E), and the arterial wall thickness (a), and inversely as the square root of the specific gravity of

FIG 3 Curve expressing mathematically the elastic characteristics (q) of the aorta at different ages (abscissae) (after Frank)

It can safely be predicted that systematic use of this method in post-mortem studies of large arteries from subjects who had arteriosclerosis and hypertension would yield part of the information still needed to explain both the cause and the dynamic effects of hypertension.

Studies on Vessels in Situ Accord-

*Since the parameter q has no absolute value it has been given the arbitrary value 1.5 when specific tension equals 1.5×10^6 dynes. The formula expressing the elasticity coefficient at this pressure then becomes $E_{1.5} = E_0 \times \sigma_{1.5}^2$

blood (s) and the diameter of the vessel (d). Assuming all factors except E to remain constant or to be inconsequential, an inverse relation obviously exists between pulse velocity and arterial elasticity.

It is therefore not surprising that many investigators have attempted to study the elastic condition of arteries *in situ* by measuring pulse velocities. While there appears to be general agreement in the conclusion that the pulse velocity progressively increases with age, an examination of the many

data upon which such statements are based reveals many discrepancies both as to what constitutes a normal velocity and as to the magnitude of the increase with age. Figure 4 shows velocities reported by three groups of workers in comparison with values calculated by Frank on the basis of elasticity studies of human aortas. The great differences shown require no further comment. Likewise, while the majority of observers claim that the pulse is propagated faster in cases of demonstrated arteriosclerosis, nephritic hypertension, etc. (Friberger, 1912, Munzel, 1912), Sands (1925) was unable to corroborate these results. My own observations confirm the conclusion that the pulse velocities encountered in patients with hypertension certainly fall within the ranges found yearly in young, healthy medical students.

The variable results arrived at by different investigators are partly due to the methods and procedures employed

in estimating pulse velocities; partly also to the fact that pulse velocity is affected by the size of vessels (Bazett and Dyer, 1922; Sands, 1925) and by the height of diastolic pressure (Frank, 1927, Bramwell, Hill, McSwiney et al., 1922-1923). Improvements in technical methods for pulse registration have reduced to a minimum the errors incident to accurate calculations of pulse delay between two points. Unfortunately, it remains just as difficult to measure with exactness the arterial distance traversed by the pulse wave. The possibility of error thus introduced becomes even greater when vessels are tortuous. The variations in size of vessels resulting from muscular contractions or pathological processes are also beyond our present means of study and evaluation (cf Lyon and Sands, 1924).

Bramwell, Hill and McSwiney (1922, 1923, 1924) have made earnest attempts to take variable diastolic pressures into account and to this end have

FIG. 4 Chart giving pulse velocity data at different ages according to Friberger (Fb), Bramwell and Hill (B), Sands (S), compared to calculated velocities of Frank (F) for internal pressures of 100 mm Hg

introduced an ingenious yet simple method by which the *effective* diastolic pressure in a short length of artery can be altered at will. This was accomplished by applying a positive or negative counter pressure over a brachial or radial artery through an elastic cuff or chamber and calculating the velocity of the pulse wave in the short length of vessel submitted to such positive or negative pressures. In this way, the pulse velocities at pressures above and below existing diastolic pressures could be calculated according to the formula

$$V = \frac{d}{y-x} \left(\frac{1-d}{1} \right)$$

where x equals transmission time between two points distant l from one another and y the time between same points when a bandage of length d is applied. By applying a simplified formula,

$$\frac{\text{percentage increase in volume per mm rise of pressure}}{127} = \frac{127}{\text{Velocity in meters/sec}},$$

the extensibility at different diastolic pressures could be determined and plotted in the form of curves. Finding good agreement between average velocities in vessels *in vivo* and others on isolated arteries, Bramwell, Hill and associates concluded that it is possible to evaluate changes in elasticity of vessels *in situ* by such means.

The method, however, appears to have several shortcomings. (1) The actual length of artery compressed and hence the pulse velocity in it cannot be determined with great exactness, (2) the extensibility curve derived applies only to the vessel examined and not to the aorta or arterial system as a

whole, and (3) the extensibility curves of similar arteries are apparently not the same in normal individuals. Thus, Hemmingway, McSwiney and Allison (1928) recently found great differences, both in pulse velocities and extensibilities of normal brachial arteries. A series of these curves, reproduced in figure 5, indicates that the arteries of normal individuals fall into three groups, viz, super-extensible (S), normal (N) and hypo-extensible (H) and furthermore that the mean pulse velocity at corresponding effective pressures (lower set) varies a great deal.

I have set forth briefly the difficulties that discourage the use of pulse velocity determinations in evaluating the elastic state of vessels *in situ* not with the purpose of detracting from the sincere attempts made to overcome great physical difficulties, but rather to

give you an idea of the obstacles that still remain to be surmounted.

THE FUNCTIONAL NATURE OF INCREASED PERIPHERAL RESISTANCE

Morphological changes in the peripheral arterioles with reduction or obliteration of their lumen rarely if ever account entirely for the increased peripheral resistance encountered during hypertension. Endarteritis is rarely universal; not infrequently it is limited to individual organs such as the kidneys, pancreas, spleen, etc. Moreover, even after mechanical deletion of large portions of the natural circula-

lation, physiological compensatory mechanisms, both nervous and mechanical, are able to reestablish arterial pressures at approximately normal levels. For example, it is possible in dogs to ligate one common carotid, both subclavian and internal mammary arteries and, in addition, the aorta above the renal arteries without causing a rise of blood pressure that lasts more than ten or fifteen minutes.

Consequently, the conclusion appears justified that increased peripheral resistance sufficient to bring about prolonged or permanent elevation of pressures must be due either (a) to excessive generalized functional contraction of arterioles or (b) to failure of

the reflex mechanisms which normally moderate blood pressures. The agents which cause such vascular constriction and the mechanisms involved remain shrouded in mystery; indeed, it is not improbable that they are many and varied. Time is lacking to review the many chemical, hormonal and nervous theories that have been advanced to account for the generally contracted state of peripheral arterioles. Fortunately, this is not vital, however, as the reader may refer to the excellent monograph of Gager (1931) for a discussion of this aspect of the subject. The possibility that unbalanced reflexes rather than specific chemical stimulations of arterioles or their controlling nerve

FIG 5 Graphs showing arterial extensibility (upper curves) and pulse velocities (lower curves) in normal individuals at effective diastolic pressures indicated on abscissae S, super-extensible type, N, normal type, H, hypo-extensible type—(after plots from Mc-Swney et al)

centers may play a rôle in some forms of human hypertension is suggested by recent experimental work. Denervation of the sinus caroticus and section of aortic nerves can provoke a state of hypertension accompanied by notable increase in cardiac size (Koch, Mies and Nordman, 1927, Regniers, 1930). Mechanical obstruction to flow in abdominal viscera and perhaps in the heart may likewise set vasomotor reflexes in operation which if uncompensated may result in persistent hypertension (cf Hering, 1930).

HEMODYNAMIC AND CARDIODYNAMIC EFFECTS OF INCREASED ARTERIAL RIGIDITY

Arterial Pressures and Flow
Mathematical calculations and physical experiments lead to the conclusion that increased rigidity of large blood vessels causes an elevation of systolic and a decline of diastolic pressures at a constant cardiac rate and output. The arithmetical mean pressure is reduced somewhat. Fahr, Davis, and Spittler (1931) have demonstrated that similar changes occur in a heart-lung preparation so arranged that the volume-elasticity coefficient of the arterial system could be increased or decreased at will. However, the pressure changes reported were doubtless exaggerated a great deal through the maximum and minimum valved mercury manometers employed.

I have recently reinvestigated the circulatory effects produced when the elasticity of the aorta was decreased by treatment with formalin. The aorta from a large dog, after removal from the body and ligation of all branches, was inserted into an artificial circuit

in which pressure variations resembling those found in normal animals were reproduced artificially. In such a system the pressure head, heart rate, periods of ejection and peripheral resistance could be kept constant while the elasticity of the aorta was changed by perfusion with formalin solution. Optically recorded pressure curves before and after formalinizing the aorta are shown in segments D, E and F of figure 6. They demonstrate that the more rapid decline of pressure during diastole and the consequent lowering of diastolic pressure are the only changes as long as the pressure head remains constant. The explanation is simple. Through a reduced expansion of the aorta by an equal pressure head, less blood is accommodated during mechanical systole and a larger volume moved forward. Consequently the tubes contain less fluid at the beginning of mechanical diastole and reach their normal state more rapidly, with the result that arterial pressure falls quickly and to a lower level. The stream distal to a peripheral constriction, i.e., in the capillaries, becomes less and less constant as elasticity diminishes and with very rigid vessels acquires a pulsating character. The minute flow also decreases. Such physical experiments demonstrate how a capillary pulse and collapsing arterial pulse can be dynamically produced without change in peripheral resistance or without occurrence of valvular insufficiency. The practical conclusion is derived that the collapsing character of clinical pulses during aortic insufficiency becomes greatly intensified when sclerosis of the aorta coexists.

Dynamic Effects on Left Ventricle

FIG 6 Aortic pressure curves from a dog's aorta in an artificial circulation machine A, control conditions, minute volume, 630 cc, B, after increased peripheral constriction, minute volume, 350 cc, C, after raising pressure head, minute volume, 420 cc D, same conditions as B, E, 10 minutes after applying formalin to aorta, minute outflow 290 cc, F, 3 hrs after formalin treatment, minute outflow 240 cc, G same conditions as F but with increased systolic pressure head, minute outflow 310 cc Peaks x are accentuated waves (possibly reflected waves) superimposed on fundamental forms Time 1/5 sec

The total internal energy transformation during each heart beat is largely degraded into heat, less than 20 per cent manifesting itself as useful external work

The work of the left ventricle is conveniently, though somewhat roughly, calculated as the product of mean pressure and quantity of blood ejected Using such a formula, Fahr, Davis and Spittler (1930-31) concluded from experiments on heart-lung preparations that since neither factor changed significantly, the external work of the heart is practically unaffected through

an increased elasticity coefficient of the arterial system

The total energy utilization can be found directly only from studies of oxygen consumption by the heart Such determinations still need to be made Starling and Visscher (1927), however, observed quantitative relations between changes in oxygen consumption and diastolic size and Fahr et al (1931) noted that the diastolic size remained unaltered when the volume elasticity coefficient of the arterial system was increased Therefore they tentatively concluded that the total en-

ergy consumption of the heart is little, if at all, affected

These deductions, however, square neither with *a priori* considerations nor with physical experiments. Any augmentation of arterial systolic pressure obviously presupposes a corresponding elevation of left ventricular pressure. It is difficult to visualize how this can come about without additional expenditure of energy if, as experiments indicate, systolic discharge remains the same. Physical tests show definitely that the minute volume flowing through less elastic tubes can be restored to normal only by increasing the pressure head. Thus in the experiment illustrated by segments D, E and F, figure 6, the minute outflow decreased progressively from 340 to 240 c c, but by elevating the pressure head and thereby both systolic and diastolic pressures as shown in segment G the outflow was increased again to 310 c c. The faultiness of Fahr, Davis and Spittler's recent conclusions appears to arise from use of an arithmetic mean pressure in calculating the work of the left ventricle and in ignoring entirely the velocity factor. Katz (1932) has recently again pointed out how great and variable the error may be, even when mean pressure and mean velocity are both used in work calculations. The tendency is to under-estimate both the pressure and velocity energy and to alter their distribution so that the per cent calculated as kinetic energy seems less than it really is. On a previous occasion Fahr (1927) himself recognized that such calculations are only approximations and suggested the integral

$$\int_{P_1}^{P_2} p \, v \, d + \frac{sv}{2g}$$

Using this integral, Fahr (1927) also arrived at the conclusion on theoretical grounds that arteriosclerosis increases the work of the left ventricle but only insofar as it necessitates increased systolic pressures.

A critical evaluation of existing theory and fact therefore makes it improbable that an increased elasticity coefficient of the aorta is without effect on the total energy expenditure or external work of the left ventricle, though it is probable that the magnitude of the increase need not be very great with the degree of rigidity ordinarily attained.

Hemodynamic and Cardiac Effects of Increased Peripheral Resistance
Increased arteriolar resistance affects hemodynamics primarily by reducing the minute efflux from the arterial system. As a result, systolic and diastolic pressure are both elevated and the amplitude of the pressure variations is reduced. In other words, the effects on pulse pressure are just the reverse of those produced by decreased elasticity of large vessels. The significance of the physical changes in systolic and diastolic pressures are demonstrated by experiments on a dog's aorta. As shown in figure 6, A and B, augmented peripheral resistance decreases the rate at which pressure declines during diastole and elevates the diastolic pressure when the pressure head (i.e., systolic pressure) is kept constant. Coincident with these changes in pressure the peripheral outflow decreased from 630 to 350 c c per minute. When the pressure head is elevated, both systolic and diastolic pressures rise together but the pulse pressure still remains less than normal. As illustrated in figure 6, C, even this elevation of

pressure head was unable to restore the minute outflow to normal, for it was only 420 c c per mm. at the time this tracing was recorded. Such physical experiments demonstrate clearly that the rise in diastolic pressure reflects primarily the magnitude of the peripheral resistance change and that a considerable elevation of systolic pressure is needed in order to restore the capillary bloodflow to normal

The manner in which the heart accomplishes this can fortunately be studied in animals whose peripheral resistance is acutely increased either mechanically by compression of the abdominal aorta or more physiologically by generalized vasoconstriction. The latter is easily accomplished reflexly by stimulating the central end of a vagus nerve. The changes in central pressure pulses produced by such stimula-

tion are illustrated by segments A, B and C in figure 7. We note that contrary to physical experiments, the pulse pressure increases and that systolic pressure rises more than diastolic. The preliminary vibration (a) occurring during the isometric periods becomes more intense and the height of the primary upstroke (b) increases. All of these characteristics clearly indicate that the ventricular contractions were more vigorous.

The mechanisms by which this is accomplished were studied by Katz and myself.* These investigations demonstrated that increased peripheral resistance causes an immediate but transient decrease in systolic discharge

*For details cf Wiggers, *Circulation in Health and Disease*, 1923, p 113, *Pressure Pulses in the Cardiovascular System*, 1928, p 132

FIG 7 Subclavian pressure curves recorded by optical manometer from a dog. A normal pressure pulse, B and C at various stages during increased peripheral resistance produced by central vagus stimulation. Time 02 sec

with the conversion of more kinetic energy into pressure energy. The residual blood which thus accumulates from beat to beat, added to normal inflow from the left auricle, quickly increases diastolic ventricular size and elevates the initial tension. This acts as a stimulus to cardiac muscle, in consequence of which systolic volumes again equal or even exceed the normal, depending on the intensity of the peripheral change.

Wiggers and Katz (1928) have further studied how the economy of ventricular effort is affected under such conditions. This was done by determining the ratio between the static effort and dynamic effort of the left ventricle during the period of ejection. To do this, we calculated by analysis of optical pressure curves how much of the total pressure energy during the ejection period is required to support the arterial pressure in the aorta statically and how much is stored during systole for conversion into energy of flow during subsequent diastole. Our results show that increased arterial resistance not only augments the external work of the heart but also decreases the economy of effort. We also found, however, that the increased diastolic size and initial tension supplies a mechanism whereby the economy of effort is approximately restored to normal.

Summarizing, the accumulation of residual blood which temporarily follows increased peripheral resistance acts successively to increase the diastolic size and initial tension and to restore both the systolic output and the economy of effort to normal. Through these physiological compensatory

mechanisms systolic arterial pressure is elevated until the capillary volume flow is again normal.

PHYSIOLOGICAL FACTORS IN CARDIAC HYPERTROPHY

Growth implies increased metabolism. Increase in bulk of muscular elements, i.e., hypertrophy, must therefore be preceded by increased metabolic rate. The experimental results of Starling and Evans and Starling and Visscher make it extremely probable that, as far as the heart is concerned, oxygen consumption is related solely to changes in diastolic volume. Hence, of the many theories proposed to explain cardiac hypertrophy, the conception that it is caused by a previous increase in initial tension and diastolic stretch appeals most to a physiologist. Since only a moderate increase in peripheral resistance is required to produce such changes in diastolic size and since the elasticity coefficient of the larger vessels must be considerably augmented to effect a much smaller ventricular distention, the conclusion follows that alteration in caliber of peripheral vessels is ultimately the predominant factor responsible for the left ventricular hypertrophy so common in patients with persistent hypertension.

This is not the occasion to discuss the many theories proposed to explain ventricular hypertrophy. It may be stated in passing, however, that the view of Holman (1925) which associates hypertrophy with movement of increased minute volumes by the ventricle, certainly cannot account for hypertrophy secondary to hypertension. Neither animal experiments nor

observations on patients with hypertension give any evidence that the minute volume is significantly increased (see below)

Hypertrophy is so commonly regarded as a pathological and harmful process that its beneficial character is generally forgotten. The physiologist looks upon hypertrophy as a normal functional response to increased stretch, regardless of whether this is secondary to physiological or pathological changes in the circulation. In a sense, the normal left ventricle is physiologically hypertrophic. At birth the weights of the two ventricles are very nearly equal but, owing to a progressively greater peripheral resistance and diastolic stretch, the left ventricle slowly increases in bulk. The question may therefore be raised whether an additional increase in left ventricular bulk during hypertension cannot also be considered a physiological rather than a pathological reaction. It is true that deleterious influences primarily responsible for changes in diastolic size and hypertrophy may also effect the myocardium, producing structural differences in heart muscle cells which are superadded to, but not fundamentally a part of, the hypertrophic process *per se*.

THE PHYSIOLOGY OF CLINICAL HYPERTENSION

By far the majority of clinical investigators are rapidly arriving at the conclusion that changes in arteriolar resistance are mainly, if not solely, responsible for the hemodynamic alterations in clinical hypertension. This view is summarized with great positive-

ness, for example, by Weiss and Ellis (1930).

"A satisfactory explanation of the dynamics of the circulation in patients with hypertension is that due to the abnormally accentuated arteriolar resistance, a high arterial and arteriolar pressure is essential to establish the normal capillary bloodflow pressure in the vital organs. The measurements and observations do not bear out the observations that loss of elasticity of the great arteries, or increased cardiac output or increased circulatory volume - - - is responsible for the pressure of hypertension."

We have substantial experimental evidence for the conclusion that sclerosis of large central arteries, on one hand, and increased peripheral resistance on the other hand not only affect the left ventricle to different degrees but that they produce directly opposite effects on arterial pulse pressures and diastolic pressures as well. With this as a criterion we may properly inquire whether clinical forms of hypertension fall naturally into two such physiological groups or whether a combination of peripheral and central effects generally obtains. In scanning the records of patients with hypertension in the wards of Lakeside Hospital with the view of selecting certain types for more detailed physiological study I am continually impressed with the fact that the majority of subjects have large pulse pressures and high diastolic pressures. Except when complicated by aortic leaks, the patient with low or even normal diastolic pressure readings is rare indeed. These personal impressions are confirmed by a review of cases of hypertension reported in the literature. Let us take several examples. Hochrein (1928) tabulated 66 cases, exclusive of those with auricular

fibrillation In 58 of these, pulse pressure exceeded 58 mm , in 21 cases it ranged between 58 and 80 mm , in 22 cases, between 80 and 100 mm , and in 12 cases, between 100 and 135 mm In none of the 66 instances reported was diastolic pressure below 80 mm

tology and pathology can easily be duplicated from many other sources

The following simple tabular summary comparing clinical blood pressure observations with experimental reactions in which one factor is varied at a time is interesting

BLOOD PRESSURE CHANGES IN HYPERTENSION

	EXPERIMENTAL INCREASE IN RIGIDITY OF LARGE ARTERIES	EXPERIMENTAL INCREASE IN PERIPHERAL RESISTANCE	CLINICAL HYPERTENSION
SYSTOLIC PRESSURE	High	High	High
DIASTOLIC PRESSURE	Low	High	High
PULSE PRESSURE	Large	Small	Large

Hg In 34 cases it was between 99 and 109 mm , in 21 cases, between 110 and 134 mm , and in 6, above 135 mm Similar data from 27 patients reported by S Weiss and Ellis (1930) reveal pulse pressure ranges from 58 to 80 mm in 9 cases, from 80 to 100 mm in 7 cases, from 100 to 145 mm in 10 cases, and a value of 205 mm in 1 case Of these, one had a diastolic pressure of 68 mm , 8 had diastolic pressures between 90 and 109 mm , 16 between 110 and 135 mm , and 2 were 139 and 160 mm , respectively Twenty-four cases of hypertension tabulated by Feil and Katz (1924) show similar though less pronounced increases Diastolic pressures were 85 mm in one case, between 90 and 109 mm in 4 cases, between 110 and 135 mm in 10 cases, and between 136 and 175 mm in 9 cases However, pulse pressures ranging between 35 and 50 were reported in 7 cases, between 60 and 80 mm in 9 cases, between 80 and 89 mm in 5 cases, and between 90 and 110 mm in 3 cases

Such uniform and consistent pressure data from patients representing great variety as to etiology, symptoma-

It suggests forcibly that the experiments which Nature is accustomed to perform on patients generally combine alterations in elasticity of central vessels with increased resistance in peripheral arterioles, the large pulse pressure being a reflection of the greater rigidity of vessels and the high diastolic pressure, of the peripheral resistance change

If this is true, subclavian pulse tracings from patients with hypertension should display deviations from normal which resemble those of segments E, F and G of figure 6, rather than those of segments B and C of the same illustration This accords with my findings in a limited number of patients studied in Lakeside Hospital Figure 8 shows two sets of such tracings, B and C from patients with hypertension, and A from a normal medical student

The tracings of curves B were obtained from an individual without palpably thickened arteries and in whom all clinical signs pointed to increased arteriolar resistance as a cause of the high blood pressure While central and peripheral pulse curves re-

FIG 8 Three sets of human subclavian pulses (S) and radial pulses (R), A, normal subject, B, hypertension, essentially peripheral origin, C, hypertension, from patient with palpably sclerotic arteries Systolic and diastolic pressures marked directly on curves in each case Time in 1/5 sec

tain many characteristic features of normal curves, the rapid decline of the subclavian pulse curve after the incisura resembles the curve of segment E, figure 6, rather than that of segment B or C. The radial pulse also shows a sharper incisura than it is customary to find in normal pulses. Reflected waves such as are commonly superimposed on normal central pulses (A) are conspicuously absent. Consequently, despite contrary clinical evidence, anyone accustomed to curve analysis cannot conclude otherwise than that some decrease in arterial elasticity must have contributed to the changes in pulse form.

In the great majority of cases examined, however, the evidence is still more conclusive. The records reproduced as figure 8, C, were taken from a man 72 years of age. The subclavian and radial arteries were hard and

thickened and the former definitely enlarged. The central subclavian pulse is characterized by the steep ascent, by the short period of systolic ejection, by the altered contour of the systolic summit, but chiefly by the great decline of pressure following the incisura. The curves clearly resemble those of G in figure 6, not those of C in the same illustration.

The radial pulse curves fail to show the customary transformation of the pulse in its transmission to the periphery, on the contrary, its contour resembles remarkably that of the subclavian. The incisura is marked and no dicrotic wave is apparent. Such a propagation of pulse waves to the periphery could be possible only through very rigid vessels.

Summarizing, the large pulse pressures, high diastolic pressures and characteristic pulse curves exhibited by

the majority of patients hospitalized as a result of hypertension definitely favor the view that alteration in elasticity of large vessels modifies and often dominates the hemodynamics of the circulation. This in no wise precludes the coexistence of increased arteriolar resistance, nor does it invalidate the generally accepted belief that the latter is the primary disturbance and chiefly responsible for the cardiac hypertrophy.

Before our conclusion can be finally accepted, however, it is necessary to exclude the possibility that the large pulse pressure and excessively high systolic pressure are not due to an increased systolic output, a possibility that is given extra weight by the facts that a hypertrophied left ventricle exists clinically and that an increased systolic discharge consistently occurs in acute experiments on animals (cf figure 7). The evidence against such a possibility can be stated briefly.

- 1 The majority of investigators (Lauter and Baumann, 1928, Burwell and Smith, 1929, S. Weiss and Ellis, 1930, Ernst and R. Weiss, 1929, Hochrein, 1928) have been unable to demonstrate increased minute volumes in patients with hypertension, by means of gasometric methods.

- 2 The venous pressures do not appear to be elevated (Hochrein, S. Weiss and Ellis) and the blood volumes are apparently not increased (S. Weiss and Ellis).

- 3 The duration of systole in relation to cycle length is also not increased (Feil and Katz) as might be expected to be the case were the systolic discharge greater.

- 4 The changes in contour of the

central pulse are not those that would be expected were increased systolic discharge the chief factor concerned. It is necessary only to contrast curves of figure 8, B and C, with those of figure 7, B and C, in which changes in systolic output were alone superadded, in order to become convinced on this point.

Careful evaluation of the experimental and clinical evidence therefore leads to the conclusion that the circulatory changes in clinical hypertension are usually produced by the combined effects of increased peripheral resistance and decreased elasticity of the aorta.

Physiological Principles in Treatment Physiologically, hypertension must be looked upon as a compensatory reaction designed to restore a normal blood supply to the tissues. As already explained, the elevation of systolic pressure is the effective force, while increase of diastolic pressure is largely a resultant of the peripheral and central vascular changes. If the physiological conception that hypertension is Nature's method of assuring an adequate blood supply to the tissues, could gain firmer root in the doctor's mind and through him be relayed to his patient, it would do much to dispel that feeling of despair and impending doom so common in the layman who learns that his blood pressure is "high." Judiciously used, the physiological conception can do much to supplant pessimism by optimism, both in patient and doctor.

The compensatory character of clinical hypertension cannot be ignored in treatment of the condition. Therapeutics as a science is steadily moving

forward. Through birth of the sister science of Pharmacology, the precise modes and places of drug action have become established, drugs with previously assumed virtues have been discarded and others with unrecognized potentialities have been given a place in therapeutics as a result of pharmacological experimentation. However, *the application of knowledge* gained through pharmacological investigations is still guided too generally by allopathic doctrines. Blood pressures are found to be high, the indications are to administer drugs which pharmacological research assures us will lower it—so runs the allopathic philosophy. A great scientific principle is forgotten, viz, that guidance and treatment can ordinarily accomplish no greater good than to assist the compensatory or curative processes that are naturally called into play. Certainly any remedy or agent that thwarts the natural compensatory processes should be employed only advisedly.

The question may now be raised whether it is advisable to lower blood pressures in hypertension unless real dangers appear to be impending. S. Weiss and Ellis justly warn that "therapeutic procedures which lower blood pressure through decreased cardiac output can only be harmful." But the indiscriminate use of vasodilating drugs is equally undesirable. Their effect on blood flow through an organ is always the resultant of two actions, viz, the local change in caliber of vessels and the degree to which pressure is lowered in the aorta. Now it is a fact that vasodilator drugs without exception act predominantly on those arterioles that possess the great-

est number of muscle fibers. For example, they affect vessels of abdominal organs more than vessels of the heart and brain, hence the flow through the latter is determined by the change in aortic pressure rather than by local variations in caliber. I have repeatedly demonstrated experimentally, for example, that amyl nitrite, contrary to general belief, reduces bloodflow through the coronary and cerebral vessels.

Obviously such lowering of blood pressure defeats the purpose of natural compensatory mechanisms, and at times may actually be dangerous. An experimental observation may be added to emphasize this statement. When the abdominal aorta of a dog is occluded for an hour or more and the compression then released, aortic pressures fall to very low levels and the animal soon dies of circulatory failure. Erlanger attributed these reactions to shock resulting from prolonged anoxemia of tissues, but my own evidence shows convincingly that the marked fall of pressure is directly due to myocardial failure. Venous pressure rises, it does not fall as in shock, the small cardiac ejections are due to impaired contraction, not to deficient filling as in shock. The reduced coronary flow following the sudden decrease in aortic pressure after decompression is undoubtedly the factor that initiates the myocardial failure. Little imagination is required to suggest how much more serious a sudden decrease of aortic pressure might be if coronary vessels are sclerosed in addition.

There can be no doubt that the patient with great hypertension is confronted with certain risks, such as rup-

ture of blood vessels or decompensation of the heart. But physiological considerations suggest that in attempting to avoid these dangers the wise

physician will consider carefully whether an even greater risk is not incurred through the use of drugs which lower systemic pressures generally.

Essential (Primary) Hypertension: A Clinical and Morphological Study of 375 Cases*†

By FRANCIS D MURPHY, M S, M D, F A C P, JOHN GRILL, M D,
BENJAMIN PESSIN, B S, M D, and GAIL F MOXON, A B, M D,
Milwaukee, Wis

THE variety of symptoms and vascular lesions associated with essential hypertension is so great that consecutive stages of the disorder may appear at times to be diseases of different kinds. Most cases of essential hypertension conform to the usually well recognized course of chronic hypertension which terminates, after years, in heart failure, cerebral hemorrhage, renal failure or some intercurrent infection. But there is a small group of cases, which, because of the peculiarities of the symptoms and vascular lesions, has been set aside by some observers in a separate class and designated "malignant" hypertension. Over the pathogenesis of the arteriolar lesions in this group, especially in the kidney, considerable controversy has arisen.

As early as 1910 Volhard and Fahr¹ differentiated the red granular kidney

from the genuine contracted kidney leading to renal insufficiency. They² later clearly distinguished two forms of essential hypertension (a) the benign form characterized by arteriosclerosis of the small renal arteries and (b) the malignant form or the combination form distinguished by the addition of an inflammatory factor to the kidney already damaged by arteriosclerosis. Although there has been objection to the use of the terms benign and malignant in connection with cases of hypertension, they have become so well established in the literature that it is difficult to discuss hypertension without referring to them. The division of cases of hypertension into benign and malignant forms is convenient. But it must be recognized that benign cases may end fatally in uremia, the benign case may become transformed into the malignant one; there may be intermediate cases having features of the benign type with a few of the characteristics of the malignant form, and finally that there may be degrees of intensity of the symptoms and vascular lesions within the malignant group.

In this report an analysis is presented of the clinical and postmortem

*From the Departments of Medicine and Pathology of Marquette University School of Medicine, and the Medical Clinics of the Milwaukee County Hospital, Milwaukee, Wis.

†Presented at the San Francisco meeting of the American College of Physicians, April 6, 1932.

data obtained from a study of 375 cases of primary (essential) hypertension. An attempt is made to show that the varieties of clinical and morphological changes observed are manifestations of the different stages of one process. In order to obviate the impression that the cases with an intense and rapid course may be considered as a separate condition, and to emphasize the unity of the clinical and morphological features, all cases are divided into three groups corresponding to three consecutive stages of the disease. This grouping is unimportant except that it is of immediate convenience. Cases of early hypertension in which symptoms appear to be independent of the vascular lesions are placed in group 1, this may be called the functional stage.

In group 2 are the cases in which hypertension is associated with definite arteriosclerosis slowly progressing to the breakdown of essential organs; this may be designated the arteriosclerotic stage. And finally, in group 3, are the cases of so-called malignant hypertension. Corresponding to the stormy clinical course are the necrotic lesions in the arterioles of the kidney and other organs; hence the term arteriolonecrotic stage may be appropriate for this group.

MATERIAL STUDIED

For the purpose of this report cases were included in which there was a persistent systolic blood pressure of 160 mm of mercury or above, and a diastolic pressure of above 100 mm of

FIG 1 (Group 1) Normal glomeruli and arteries seen in group 1

mercury Cases of glomerular nephritis, toxemia of pregnancy, hyperthyroidism and aortic regurgitation were excluded, as well as any other case in which the cause of the hypertension was apparent

Hypertension, without clinical evidences of arteriosclerosis other than those seen in normal people, was the chief feature of cases in group 1 There were no symptoms or signs ordinarily present in cardio-vascular-renal disease Symptomatically a vasomotor derangement of the type often seen in neurasthenia was the essential change Frequently there were no symptoms Patients died of causes independent of cardio-vascular-renal changes, an accident, an operation, or an intercurrent infection was the chief cause of death There were 43 cases in group 1 In group 2 the cases are recognized as those having arteriosclerosis of peripheral as well as internal arteries This group represents a stage of slow progression and the symptoms are those produced by arteriosclerotic narrowing of the lumina of arteries leading to ischemia and slow fibrosis of internal organs Heart failure, cerebral acci-

dent, renal failure and thrombosis may appear in this stage There were 303 cases in group 2 The remaining 29 cases were placed in group 3 Clinically the patients of the last group had the following distinctive features a) persistent excessive hypertension, b) violent headaches, c) rapid progressively downward course, d) sudden loss of weight and strength, e) typical retinal changes, f) a course resistant to treatment, and g) a termination with a functional breakdown of some essential organ, usually the kidney or the heart Histologically there was an advanced severe diffuse arteriosclerosis with necrotic lesions of the arterioles of various organs A detailed analysis of the clinical and histological features of 12 of the 29 cases included in group 3 was reported previously by Murphy and Grill³

ANALYSIS OF CLINICAL DATA

The causes of death in this series as well as the number and percentage of each are arranged in five groups as shown in table 1 Heart disease caused death in 188, or 50 per cent of all cases It is seen that 171, or

TABLE 1
CAUSES OF DEATH IN 375 AUTOPSIED CASES OF ESSENTIAL HYPERTENSION

	GROUP I		GROUP II		GROUP III		TOTAL	
	NO	PER CENT	NO	PER CENT	NO	PER CENT	NO	PER CENT

2 RENAL FAILURE	0	0	23	7.6	16	55.2	39	10.4
3 APOPLEXY OR THROMBOSIS AND EMBOLISM	0	0	45	14.9	5	17.2	50	13.4
4 INFECTIONS	12	27.9	40	13.2	1	3.5	53	14.2
5 MISCELLANEOUS	21	48.8	24	7.9	0	0	45	12.0
TOTAL	43	100.0	303	100.0	29	100.0	375	100.0

56.4 per cent of cases, in group 2 died of heart disease while in group 3 only 7, or 24.1 per cent, had heart failure. Ten patients, or 23.3 per cent, of group 1 died of heart disease but usually of a type produced by infections and not hypertension. In sharp contrast to the percentage of deaths caused by heart disease was the low mortality rate from renal failure. Thirty-nine only, or 10.4 per cent, died from renal failure. Of these 23, or 7.6 per cent, occurred among cases of group 2, 16, or 55.2 per cent, among those of group 3. In group 2 uremia followed a slowly progressing renal failure, but in group 3 uremia developed suddenly and caused early and rapid death. It was unexpected to find that only 45, or 14.9 per cent, of the patients in group 2 died of cerebral hemorrhage or thrombosis, while in group 3 five deaths from apoplexy, or 17.2 per cent, were not exceptional. Of the infections which caused death in 53 cases, or 14.2 per cent, pneumonia was the most prominent. Erysipelas and gangrene of the feet occasionally occurred.

The ages of the patients ranged from 9 to 100 years. They are arranged ac-

cording to decades and the number and per cent in each group are given in table 2. In group 3 (malignant), 62.3 per cent of the individuals were under 50 years of age; while in groups 1 and 2 (benign), 16.3 per cent were under 50 years of age. In order to emphasize this interesting comparison the age incidence was arranged as shown in table 3. The occurrence of so many patients of advanced years may be explained by the fact that many of the patients were inmates of a county infirmary.

Throughout the three stages there were two unifying clinical factors, hypertension and left ventricular hypertrophy. The length of time elapsing between the onset of hypertension and the occurrence of other symptoms was unknown in most cases. However, in some cases it is known that as short a time as one year, and in other cases as long as 15 years, elapsed before the usual symptoms developed. The degree of hypertension in groups 1 and 2 varied considerably, fluctuating in some cases between 150 mm and 300 mm. of mercury systolic, and from 100 mm to 160 mm. of mercury dias-

81-100	30	0
TOTAL	318	29

tolic In group 3 this changeableness was less noticeable. The accompanying symptoms appeared to bear no relation to the height of the blood pressure in any group. In group 2 a few patients were observed who showed systolic pressures above 200 mm of mercury and independent of treatment had normal pressures with no heart failure within a period of one year. Of the 303 cases in group 2, 32 or 10.5 per cent had no hypertension during the last period of observation preceding death. Previous records in some of the cases proved hypertension to have been present on former observations. In other cases, evidences such as cardiac hypertrophy, retinal and peripheral arteriosclerosis, as well as arteriosclerosis of the smaller arteries in the kidney were taken as proof of a pre-existing hypertension. Obviously the blood pressure dropped in many cases of coronary disease and myocardial failure.

Left ventricular hypertrophy was present at autopsy in 263, or 79.4 per cent, of all cases, there was no record in 44 and in 68 cases no enlargement was present. Of the 263 cases of proved left ventricular hypertrophy, only 182 were recognized clinically, in-

dicating a considerable disparity between the clinical and postmortem figures. The two chief clinical manifestations of heart disease were angina pectoris and the syndrome of left ventricular failure. The frequency of angina pectoris was difficult to determine because patients were frequently unable to distinguish between pain in the cardiac area and other sensations often produced by left-sided heart failure, such as constriction, heaviness, distension, and suffocation in the sternal region. It was estimated that 42, or 11.2 per cent, of the 375 patients had angina pectoris. Pain in the heart area was the first symptom of heart disease in approximately 18, or 5 per cent, of all patients having heart failure. The syndrome of left ventricular failure was the outstanding feature. Of the 188 patients dying of heart disease it was the first evidence of any disorder noted by the patient in 105, or 55.8 per cent. This classical syndrome developed in every case of heart failure from hypertension. It was characterized by paroxysmal dyspnea usually worse at night, palpitation of the heart, and a sense of distress in the heart area. Dyspnea, usually nocturnal at first, was the earliest symp-

tom of heart failure in most cases although attacks of dyspnea varied in time and duration; as a rule, they persisted for about twenty minutes in the earlier stages and then subsided only to return about the same time the following night. Frequently patients worked during the day without experiencing recurrent attacks. After some weeks or at times months, attacks came during the day and recurred so frequently that the patient was confined to bed. With the onset of this type of dyspnea, the outlook for the patient was distinctly bad, a few patients, however, recovered and lived only to die of heart failure or apoplexy in later years. Palpitation, although frequently present,

was the first symptom in only a few cases.

Murmurs were most frequently heard at the mitral area, being recorded in 85 cases, or 22.6 per cent of all cases. Aortic systolic murmurs were less common, being noted in 52, or 13.8 per cent of cases. A soft diastolic aortic murmur transmitted down the left sternal border was occasionally found. Of greater importance than murmurs was the frequent presence of a gallop rhythm. It was noted in 95, or 50.5 per cent, of the 188 cases of heart failure. Usually the onset of gallop rhythm indicated a progressive left ventricular failure. A few exceptions to this rule were observed.

FIG 2 (Group 2) Focal thickening of the capillary basement membrane with mild arteriosclerosis. Azo-carmin stain.

Electrocardiographic examinations revealed a variety of changes. The most common were left ventricular preponderance and evidences of left bundle branch block, many were normal.

Although an arteriosclerotic contracted kidney was commonly found at autopsy, uremia was a rare complication, occurring in only 39, or 10.4 per cent, of all cases.

Clinically the following renal functional tests were used routinely in all cases. (a) phenolsulphonphthalein test, (b) urea concentration test of McLean, (c) dilution and concentration tests of Volhard, (d) blood nitrogen estimations weekly, (e) the urea clearance test was used to some extent during the past two years and was found to be the most satisfactory one in giving information of early renal failure. In group 3 the kidney destruction from the necrotic and thrombotic complications of the arteriosclerosis was associated with sudden and early uremia, while in group 2 the ischemic atrophy of the kidney was a slower process taking months and years completely to render the kidneys insufficient. Albuminuria was a constant feature of cases in both groups having renal failure. There was, however, a difference in the response to treatment of the renal failure in the two groups, renal failure in group 3 was decidedly resistant to treatment while that in group 2 frequently appeared to be benefited by treatment. Frequently albumin was found independent of casts, red blood cells and pus cells. In such cases the albuminuria was assumed to be caused by renal congestion from a failing heart.

The presence of small quantities of albumin associated with many red cells and pus cells was considered to be evidence of small infarcts due to arteriosclerotic occlusion of smaller arteries. Heavy albuminuria with casts, red cells and pus cells was found with renal failure in both groups 2 and 3. Extrarenal factors, such as heart failure and infections added to kidneys already damaged by arteriosclerosis, occasionally caused renal failure. Edema of the nephritic type did not occur in this series. There was no hypercholesterolemia present and doubly refracting lipoids were not found in the urine of patients suffering from edema. The albumin and globulin content of the blood was always normal in cases in which estimations were done. Edema, when present, was of the cardiac variety. Although pallor of the skin was noticeable in many cases, anemia was infrequent except in cases of renal failure when it was observed in some but not all cases.

Apoplexy was the cause of death in 50, or 13.4 per cent, of the cases. Hemorrhage in other parts of the body was occasionally observed. There were two cases of renal hemorrhage, one case had hemoptysis and autopsy revealed no pulmonary tuberculosis or any disease aside from arteriosclerosis. Hematemesis was observed once in this series. Epistaxis was more frequent. Vascular crises producing transient hemiplegia or aphasia with monoplegia were observed four times. In a few cases in group 3 there were periodic attacks of abdominal cramps and of severe headache. Such attacks were believed to be caused by vascular crises involving visceral arteries of the ab-

domen and of the brain respectively. These periodic attacks remained for periods varying from several hours to several days. There were two patients belonging to group 3 who developed hemorrhages into the skin resembling purpura hemorrhagica. The lesions varied in size from several millimeters to large blotches of several centimeters in diameter. The disease in both instances progressed rapidly to a fatal termination.

RETINAL CHANGES

Recent work done in this country chiefly by O'Hare and Walker,⁴ Keith, Wagener and Kernohan⁵, Fishberg and Oppenheimer,⁶ and Wagener,⁷ has established the relationship between the various stages of hypertension and the changes in the arterioles of the retina. In accordance with other observers we have found the vascular changes in the retina one of the best indicators of the degree of vascular changes throughout the body. For the purpose of prognosis the retinal lesions in group 3 are of considerable importance.

In the cases of early essential hypertension (group 1) the retinal examinations revealed no abnormalities. In cases of longer duration, evidences of arteriosclerosis were usually present. Narrowing of the arterioles with increase of the light-reflex of the arteries, tortuosity of the arteries and arteriovenous compression were the usual features. Occasionally, there were small hemorrhages along the course of some vessels and at times white patches were seen produced probably by an old healed hemorrhagic area. The disks in this group were clear and edema of the retina was

mild. By observing these eye changes from time to time the rate of progress of arteriosclerosis may be determined. Usually the retinal arteriosclerosis in group 2 was a slowly changing process corresponding in general with the vascular changes in the kidney and in other organs of the body. The lack of destructive changes in the disks was in sharp contrast with the lesions seen in the more advanced cases of group 3 (malignant). The changes in the eye grounds in group 3 were more characteristic than in group 2. Obviously, since the vascular lesions of groups 2 and 3 are only different stages of one process, cases were seen in which the changes in the eye were of the transitional form corresponding to the type termed by Wagener⁷ retinitis of severe benign hypertension. Lesions of the fundi were always found in group 3 and were characterized by papilledema, hyperemia of the disks, and constriction of the arterioles leading to the appearance of thin white lines buried in the retinal edema. Hemorrhages along the course of the arteries were frequently found. White patches were seen which corresponded to what has been designated "cotton wool" patches. These patches seemed fresher and had irregular borders that appeared to merge with the generalized edema of the retina. They lacked the clearcut glistening features of those white patches seen in the cases of group 2. In three cases in group 3 a previous diagnosis of brain tumor was made upon the changes of the eye grounds. In two of our cases in group 3, the characteristic lesions in the fundus were present before any evidence of renal damage occurred. Al-

buminuria and renal failure developed within the first few months of observation. One case in group 3 was noted in which the advanced changes in the eye grounds were absent. There was no abnormality except a mild arteriosclerosis of the retinal arteries and yet the patient died of uremia. Histologically the kidneys showed the typical arteriolonecrotic lesions seen in malignant nephrosclerosis of Fahr. When the typical retinal changes are found in the absence of renal and heart failure it is fairly certain that breakdown of the organism will follow within a period of several months. That onset of renal failure does not influence markedly the retinal picture is concluded from a study of our cases of renal arteriosclerosis with gradual renal failure in group 2. Of the 23 cases of ischemic atrophy of the kidney leading to renal insufficiency, eight were examined ophthalmoscopically. No changes were observed other than a simple arteriosclerosis. We found that the retinal vascular changes are a fair index of the lesions progressing in other organs of the body. For the purpose of exact diagnosis and prognosis

ophthalmoscopy is of no little importance.

ANALYSIS OF PATHOLOGICAL DATA

Postmortem examinations were made in all the cases. All sections were studied with hematoxylin and eosin, Van Gieson's and Weigert elastic tissue stains and Sudan III. Selected cases were studied with modified Heidenhain-Mallory stain. When fat was present polariscopic examinations were made for doubly refracting lipoids. Corresponding to the clinical groups representing successive stages of the disease, three stages of arteriosclerosis were recognized. Mild arteriosclerosis involving chiefly larger and medium sized arteries of organs such as the kidney, liver and spleen was the main feature of group 1. A more advanced arteriosclerosis of the smaller as well as the larger arteries of kidneys and other organs characterized group 2. The essential change in group 3 (malignant) was an intense diffuse arteriosclerosis extending into the smallest arteries and arterioles and producing at times an arteriolonecrosis.

As shown in table 4, cardiac hyper-

TABLE 4
HEART WEIGHTS IN 375 CASES OF ESSENTIAL HYPERTENSION

trophy was found in 263, or 79.4 per cent, of 331 hearts examined; in 44 no record was made. Slight left ventricular hypertrophy was noted in group 1; 21 of 39 hearts were above normal weight. Of 266 in group 2, 216, or 81 per cent, were hypertrophied, while in group 3 hypertrophy was present in every case recorded. Coronary disease, characterized grossly by occlusion of a large branch of the artery from thrombosis or a decided narrowing due to arteriosclerosis was recorded in 44, or 25.7 per cent, of 171 cases examined in group 2. In these cases myocardial infarcts or scars and diffuse fibrosis of the heart muscle were present. Oc-

asionally a diffuse fibrosis and scars were present when the coronary disease seemed insufficient to cause any trouble. In 4 cases the left ventricle was considerably hypertrophied and dilated and little or no fibrosis or coronary disease was found. Death was due in each case to left ventricular failure. In no case in group 3 was there macroscopic evidence of complete coronary occlusion, although coronary sclerosis with narrowing was always found. Arteriosclerotic lesions of the aortic valves leading to deformities and insufficiency were occasionally observed. Less often, the mitral valve was involved in the arteriosclerotic

FIG 3 (Group 3) Section showing the increase in the stroma, the dilated tubules, the sparsity of the glomeruli, and the extensive arteriosclerosis of the smallest arteries

process. The arterioles of the myocardium were usually normal.

The size and appearance of the kidneys were decidedly variable. Some kidneys were shrunken and granular, others were large and smooth. Microscopically arteriosclerosis of the small arteries of the kidney was constantly found. In some cases it was widespread, in others, it had a focal distribution. Variations in size, color and surface markings did not conform to any stage of the disease. Kidney weights were available in 267 cases. The average weight in 33 cases of group 1 was 181.5 gm, of the right, 176 gm, and of the left, 187 gm. In group 2, the average weight of kidneys in 205 cases was 133.5 gms, of the right, 129, and of the left, 138 gm. The largest kidney weighed 280 and the smallest 90 gms. In the 29 cases of group 3 the average weight was 115 gms, of the right kidney, 112, and of the left, 116 gms. The smallest kidney weighed 29 gms, the largest, 255 gms. In one case there was a congenital absence of the left kidney, the right weighed 255 gms.

Kidneys in group 1 were always either normal in size or larger than usual and the surface was smooth. Evidences of arteriosclerosis were confined to the larger branches, and yellowish streaks in the intima due to lipid deposits were frequently the only sign of disease. Grossly the kidneys in group 2 were of the shrunken granular type. The degree of contraction and granulation varied. Scattered scars due to healed infarcts were occasionally seen on the surface of an otherwise normal appearing kidney. The cortex of the kidneys in both

groups 2 and 3 was narrowed, and especially in group 2, accumulation of fat appeared in the renal pelvis. Kidneys of the contracted granular type were usually present in group 3. Occasionally they were larger than normal with a smooth surface or of normal size without granulation. Extensive subcortical hemorrhages were present in all but 5 cases. Small hemorrhages in the mucosa of the pelvis were constantly found, and in several cases there were blood clots with evidences of larger hemorrhages from the kidney.

Microscopically the changes in group 1 were few and were substantially the same as those in non-hypertensive individuals of the same age. The arterioles and the smaller portions of the interlobular arteries were normal. Occasionally there were areas showing arteriosclerosis of the medium-sized arteries along with foci of hyalinized and fibrosed glomeruli. Such lesions were the same as those found in the later stages, except that they were so few in number that they may be looked upon as normal. Concerning the size of the glomeruli there was no constancy. Most glomeruli were of normal size, some were hypertrophic, and a few were atrophic. The tufts undergoing atrophy showed various grades of hyaline and fatty degeneration and fibrosis. The glomeruli in many cases were further studied with the Mallory-Heidenhain azo-carbune stain, as suggested by McGregor.⁶ All of the cases in group 3 and 141 cases in groups 1 and 2 were examined with this stain. In group 1 and in some cases of group 2 representing the earlier stages of arteriosclerosis focal thickening of the

glomerular basement membrane was observed. Thickening and wrinkling of the glomerular basement membrane was noted in some cases where the smallest arteries and arterioles were intact. In more pronounced cases of contracted kidney these changes in the basement membrane were widespread and the glomeruli were more diffusely involved. Although thickening of the glomerular basement membrane was present with contraction of the renal corpuscle in some form in all cases of hypertension, such changes cannot be considered specific for cases of hypertension only, as identical changes in the basement membrane were observed in cases known to have had no hypertension. Similar changes were easy to demonstrate in kidneys of older people where the afferent arterioles as well as smaller arteries were free from arteriosclerotic changes.

In group 2 the arteriosclerosis had advanced to such extent that functional derangement of some internal organ followed ischemia. Of the lesions present in all organs, those in the kidney were found to be the most accurate index of the progress of arteriosclerosis. The predominant lesion was an arteriosclerosis of the larger and medium-sized arteries. In some cases, however, there was an extension of the arteriosclerotic process into the smaller and smallest branches of the interlobular artery. Occasionally the arterioles were involved. However, such changes were distinctly focal in distribution and frequently led to scattered renal scars. Patches of destroyed tufts were seen with corresponding tubules which showed round cell infiltration and in places advanced

fibrosis with scarring. There were many glomeruli which appeared almost twice normal size; at the same time many were shriveled and atrophic. The number of normal glomeruli depended upon the extensiveness of the arteriosclerosis. Capsular thickening was found varying from a slight proliferation of connective tissue to a thick ring of scar tissue which seemed to obliterate the capillary tuft. Associated with this were areas of interstitial fibrosis, round cell infiltration and peri-glomerular fibrosis. Hyaline and fatty degeneration of afferent arterioles with extension of the degeneration into the glomeruli were frequently seen. A distinct feature was the diffuse thickening of the capillary basement membrane. This thickening, in contrast to the earlier stage seen in group 1, was almost universal in many cases. It is obvious that within group 2 there may be a variety of histological changes depending mostly upon the extent and severity of the arteriosclerotic process. Although in groups 1 and 2 the essential histological lesion is an arteriosclerosis, the chief contrasting feature is the degree of involvement of the various organs. In group 2 the arteriosclerotic process is no longer limited to larger and medium sized arteries but in the kidney the process extends at times down to the finest vessels.

The vascular lesions of the kidney described in group 3 (malignant) have some distinguishing features which have led to their separation from the simple arteriosclerotic renal lesions under the term malignant renal sclerosis. The foudroyant destructive lesions of the kidney in group 3 were in sharp

contrast with the benign sclerosis just described. Although the clinical picture in this group was fairly uniform, the histological lesions showed various degrees of degenerative lesions. In some cases necrosis of arterioles with thrombosis of corresponding capillary loops was a frequent change, and in others an extensive severe arteriosclerosis with little or no necrosis dominated the picture. An analysis of the cases in this group suggests that the typical clinical syndrome may precede the onset of necrosis of renal arterioles. Furthermore heart failure, apoplexy, or some other complication may terminate the patient's life before renal

necrosis occurs. The renal artery was arteriosclerotic in all cases. The lumina of the arcuate and interlobular arteries were reduced in diameter in all instances due to arteriosclerosis. In all cases the cortical stroma was increased but the density varied. Focal infiltration with lymphocytes, plasma cells and occasionally polymorphonuclear leucocytes was a feature of all cases. Alteration of the tubules was constantly present. Areas of dilated tubules with low atrophic epithelial cells were adjacent to islands of compressed atrophic tubules surrounded by increased stroma. Fatty and granular degeneration of the epithelial

FIG. 4 (Group 3) Arteriolonecrosis with glomerulus illustrating necrosis in capillary loops

cells of the tubules with necrosis in some portions was frequently observed

Damage of the glomeruli was a constant change but the extent of damage varied. Many glomeruli were larger than normal and the capillary loops were normally filled with blood. Others were smaller and more cellular than normal and the loops were bloodless, and again at times the capillary loops appeared to be goiged with red blood cells. The increase in cellularity was caused by an increase in the endothelial and epithelial cells. In some places the capillary loops were adherent to the thickened Bowman's capsules. Thickening of the capsule with desquamation and proliferation of the glomerular and capsular epithelium produced crescents in some glomeruli. In other glomeruli only portions of the loops were involved leaving the remaining part of the tuft normal. Many glomeruli were reduced in size, and fatty and hyaline degeneration of the walls of the loops led to a collapse of the tuft. Hyaline droplet degeneration of the epithelium was frequently demonstrated. There was a widespread and extensive fatty degeneration of the epithelium and capillary endothelium of the glomeruli. The capillary basement membrane of the glomeruli was universally thickened and wrinkled as shown with the aniline-blue stain. In cases where death was caused by apoplexy or heart failure before uremia developed, the glomeruli were usually not so greatly damaged.

The most characteristic microscopic feature was a severe arteriosclerosis attacking the smaller and smallest arteries and arterioles of the kidneys.

The chief distinction was the diffuseness of this process. Elastic hyperplastic thickening of the arteries was present with excessive connective tissue proliferation of the intima of the smaller and smallest arteries. Fatty and hyaline degeneration of the arterioles, and especially the afferent glomerular arterioles, was an outstanding feature. In places fatty and hyaline degeneration occurred with necrosis of the arteriolar wall. In corresponding glomerular loops there was necrosis. Hemorrhagic infiltration of the necrosed arteriolar wall and of the capillary loops was a characteristic feature. The amount of necrosis, however, bore no relation to the degree of renal insufficiency, for in some cases of uremia, necrotic lesions were few and in others with intact function, necroses were numerous. More important was the diffuse intense arteriosclerosis leading to narrowing and obliteration of the lumina of the smallest arteries and arterioles with subsequent ischemia and degenerative changes in the glomeruli. There were degrees of arteriolar destruction depending upon the extent and severity of the necrotic lesions. In some cases necrosis of the arterioles was scarcely found, while in others it was widespread and severe. In one case with widespread arteriolar necrosis and many glomerular infarctions there were areas of perivascular and periglomerular leucocytic infiltration. Aside from this case no such leucocytic infiltration was observed in this series. Scattered throughout the cortex, in many cases, however, nests of leucocytes were observed.

Concerning the changes in the

media of renal arterioles, medial hypertrophy was found occasionally, usually there was atrophy of the media, and at times thickening was due to an increase of connective tissue in the media. Muscular hypertrophy was not a constant nor essential change in this group.

Histological studies were made of other organs including the spleen, lung, pancreas, and liver. In the spleen, liver and pancreas the vascular lesions paralleled those of the kidney quite uniformly. Arteriosclerosis of the smaller and smallest arteries leading to narrowing of the lumina was the chief change. Necrotic lesions were observed outside of the kidney and the eye in only two cases in group 3. In two cases a few necrotic arterioles were seen in the spleen. Pulmonary arteriosclerosis of the smallest arteries and arterioles was a rarity. In three cases there was narrowing of the arteries due to arteriosclerosis.

The arterioles of the skeletal muscle were examined in all cases of group 3 and in 124 cases of groups 1 and 2. The pectoralis major was the muscle usually examined. Hypertrophy of the media of the arterioles was constantly found in group 3. The degree of hypertrophy varied. In some cases it was so decided that the lumen of the vessel was almost closed, in others hypertrophy was slight. Moderate to advanced hypertrophy of the media of arterioles was also observed in 57 cases of group 2. Occasionally proliferation of the intima was observed in these cases.

Microscopic examination of the eye was made in two cases. The walls of the central arteries were thickened,

and the lumina of the branches, especially the arterioles, were decidedly narrowed and occasionally totally obliterated. The choroidal arterioles were variously altered, areas of fatty degeneration and of necroses were seen. In places there was a mild leucocytic infiltration of the necrotic area. The retina was edematous and many hemorrhages were seen especially in the posterior part. No degenerative changes were seen in the arterioles of the extrinsic muscles, but the media was hypertrophied. The optic nerve was edematous and there was an inflammatory exudate composed of lymphocytes and plasma cells.

DISCUSSION

The relationship of the three groups of cases of essential hypertension described here is shown by the presence of such unifying factors as hypertension, cardiac hypertrophy and arteriosclerosis, especially of the renal arteries and arterioles. Clinically and histologically the wide variety of symptoms and lesions encountered was dependent upon several factors. Chief among them was the location of the arteriosclerotic process leading to narrowing and frequently obliteration of the lumina of arteries followed by ischemia and failure of essential organs. In addition to the degree of intensity and extent of the arteriosclerosis, the speed of development of the arteriosclerotic lesions played an important part in determining the changes described. There appeared to be no constant relationship between the height of the blood pressure and the rate of progress or extensiveness of the arteriosclerosis. In some cases

there were no symptoms in the presence of extraordinarily high pressures over a period of years. Undoubtedly hypertension is an important influence in the production of arteriosclerosis, yet the inherent quality of the arteries themselves, and especially their ability to withstand strain, seems to be a more important factor. Since this paper deals only with fatal cases, obviously the study of group 1 is incomplete. Death occurred independently of the hypertension and associated vascular disorders. Ill-defined complaints or a total absence of symptoms characterized this group clinically. Histologically arteriosclerotic changes were few

and were no more extensive than those seen in non-hypertensive individuals of the same age. No case was observed in which there was no renal arteriosclerosis; but in some cases it was limited to the larger and medium sized arteries. In the succeeding stages smaller and smallest arteries were damaged. The vagueness of the symptoms in early hypertension has been emphasized by Allbutt⁹ and Mahomed.¹⁰ Moschcowitz¹¹, too, pointed out the significance of the psychic makeup of individuals with essential hypertension. More recently Ayman and Pratt¹², Davis¹³, Riseman and Weiss¹⁴, and Rolleston¹⁵ have reported

FIG 5. (Group 3) A glomerulus showing the decided thickening and wrinkling of the capillary basement membrane, typical of glomeruli in group 3. Azo-carmin stain

upon the symptomatology of many cases studied in the early stages. All of these investigators observed a parallelism between the early symptoms of essential hypertension and psychic states as seen in psychoneurotics. As emphasized by Fishberg¹⁶, it is unusual to have a case of essential hypertension come to autopsy before hypertension has done any damage to renal arteries. He did, however, study two such cases.

Apoplexy, heart failure and renal failure were the chief complications observed in groups 2 and 3. As shown in Table 1, apoplexy was the cause of death in 50, or 13.4 per cent of cases. These figures are at variance with those of Herxheimer and Schulz¹⁷ who reported that 179, or 44 per cent, of 403 cases had apoplexy. Bell and Clawson¹⁸ found apoplexy in 81, or 19 per cent, of 420 cases. The low figures in our series may be explained by the fact that we included only the primary cause of death in the analysis. For illustration, a patient may have had a cerebral hemorrhage but may have died of uremia. A comparison of the analyses of the data on the heart in groups 2 and 3 reveals that coronary thrombosis or occlusion was an important cause of death in group 2, while it was unimportant in group 3. Of 171 hearts examined at autopsy in group 2, 44, or 25.7 per cent, had coronary occlusion of sufficient extent to damage the heart and cause heart failure, or a coronary thrombosis with a cardiac infarction. Obviously coronary arteriosclerosis was more common than these figures suggest, but only the cases are included in which the coronary disease was advanced enough to produce definite heart disease and

failure. Recently Shapiro¹⁹ reported causes of death in 171 cases of nephrosclerosis. In 16 cases (9 per cent) the cause of death was coronary accident. Of 394 cases of essential hypertension studied at autopsy by Herxheimer and Schulz¹⁷ cardiac hypertrophy was present in 384 cases, or 97.5 per cent. Bell and Clawson¹⁸ reported heart failure as the cause of death in 187 of 420 cases, or 44.5 per cent. If they included the coronary group, it was stated that 254 deaths, or 60.4 per cent, occurred from heart failure. In the present study we noted that 263, or 79.4 per cent, of 331 cases had cardiac hypertrophy.

In cases of renal arteriosclerosis Russell²⁰ found no evidence of renal impairment apart from the occasional excretion of a trace of albumin; all abnormalities in the tests for renal efficiency, complicated by heart failure, she believes, were such as known to be caused by heart failure. In our 23 cases of renal failure, heart failure as an important influence in the development of renal insufficiency was excluded. Patients with a combination of heart failure and renal failure were placed in the heart failure class. That a diminished renal function may occur ultimately in benign slowly progressive forms of renal arteriosclerosis is indicated by three cases reported by Van Slyke, and others²¹. The occurrence of renal failure in the course of hypertension with renal arteriosclerosis does not indicate that the case belongs to the malignant group any more than does the onset of cardiac failure or cerebral hemorrhage. As a consequence of hypertension and arteriosclerosis the lumen of the renal

arteries and arterioles often became so narrowed that an ischemic atrophy of the kidneys followed. In sharp contrast to the cases in group 3, the process in group 2 appears to develop slowly. Histologically no necrosis is seen, but a generalized arteriosclerosis of the larger and medium sized arteries is present with a focal arteriosclerosis of the smallest arteries and arterioles. The amount of fatty and hyaline degeneration and advanced arteriosclerosis is never so extensive as in group 3. Occasionally this benign process

gradually leads to almost complete fibrosis of a sufficient number of the glomeruli to produce renal failure. We observed 23 such cases, or 7.6 per cent, in group 2. Owing to the slowness of progress of the arteriosclerotic process in group 2, patients lived longer free from complications than those in group 3. Consequently there was a decided contrast in the age incidence of the two groups as shown in table 3. Most cases of essential hypertension never progress into group 3 (malignant type), but they end fatally from some

FIG 6 (Group 3). A photograph of the eye grounds. The choked disks, the tortuous thin arteries invisible in places, the distended veins, the fresh hemorrhages with areas of white patches present a typical picture as seen in Group 3.

complication of simple arteriosclerosis in group 2. The reasons are not clear why a few patients with simple arteriosclerosis develop into the rapidly progressing type with necrotic lesions in arterioles. The explanation advanced by Volhard and Fahr² assumed that a toxic inflammatory factor was added to a kidney already damaged by arteriosclerosis. They first clearly differentiated between essential hypertension with and without renal failure and described the histological lesions found in the kidneys of each type. To the case of hypertension with simple renal arteriosclerosis with no renal insufficiency they applied the term "benign", and the term "combination form" or "malignant" was used to designate cases of hypertension which developed renal failure and uremia. They believed that the benign and malignant renal sclerosis were different forms of disease and not different stages. The considerable criticism that followed their publication dealt chiefly with their interpretation of the glomerular lesions of the malignant form. As stated by Fahr²² the clinical differentiation between benign and malignant forms was readily accepted, but a unanimity of opinion concerning the pathogenesis of the two forms was difficult to obtain. Volhard²³ stated that after the criticism of Lohlein²⁴ he concluded that an added inflammatory factor was unnecessary to explain the tissue changes in malignant form. He also concluded that the lesions are the result of vasoconstriction of the afferent glomerular arterioles with subsequent nutritional disturbances in vascular system.

Fahr²⁵ maintained his opinion that

the proliferative processes could not be produced by arteriosclerosis alone and that a toxic factor must be added. Among those who supported Fahr's theory were Von Mueller²⁶ and Meyer²⁷ and others. That the separation of the benign from malignant forms is justifiable from the clinical but not from the anatomical standpoint was held by Lohlein²⁸. He stated that one deals not with two forms but only different stages of one process. Aschoff²⁹ did not recognize a (combination) malignant form. However, he believed that a "complication" form may exist, that is, a glomerulo-nephritis may become engrafted on a pre-existing renal arteriosclerosis. Arteriolosclerosis of the kidney was a term adopted by Herxheimer³⁰ for the condition resembling malignant renal sclerosis of Fahr. He disagreed with the histological distinction between benign and malignant forms of renal arteriosclerosis, and maintained that they are terms applied to different stages of the same process and not to separate forms. Jores³¹ believed, too, that malignant and benign forms were different only in degree of arteriosclerotic involvement of smaller arteries. In the benign form he believed there was a focal arteriosclerosis of arterioles while in the malignant form there was a diffuse involvement of arterioles with disintegration of glomerular units.

In an intensive review of 420 cases of primary hypertension Bell and Clawson¹⁸ found 36 cases with renal insufficiency, 27 of the 36 cases had a slowly progressive form of renal failure ending in uremia. The remaining nine cases were characterized by uremia coming on rapidly. Histologi-

cally there was necrosis of afferent glomerular arterioles with infarcted glomeruli. In four of the nine cases, acute inflammatory changes were seen in a few glomeruli. For the nine cases they applied the term "chronic hypertension with acute uremia". The syndrome of malignant hypertension was clearly defined by Keith, Wagener, and Kernohan⁵. They described the typical retinal changes and rapid downward course in conjunction with functional failure, not of one organ, but of several organs simultaneously. In their work they emphasized the importance of finding hypertrophy of the media of the arterioles of the skeletal

muscles and of internal organs. They maintained that this hypertrophy indicates severe hypertension with diffuse vascular involvement and that the ultimate prognosis is bad.

Fishberg¹² did not see any essential difference between the benign and malignant forms. He used the term "malignant phase of essential hypertension" to describe those cases usually called malignant hypertension. The so-called malignant form, he stated, comes on gradually in the course of benign hypertension.

More recently Klemperer and Otani¹³ discussed this subject at length. In conclusion they stated that essential

FIG 7 (Group 3) Section from eye seen in figure 6. The arterioles of the retina show necrosis of the walls with almost complete obliteration of the lumina. Hematoxylin and eosin stain.

hypertension with renal failure may be associated either with a slowly progressing type of arteriosclerosis leading to renal failure or with a more rapidly developing vascular change in which severe renal atrophy is absent. This latter form is the "malignant" phase, and must be divided into two classes based on vascular lesions. In one there was necrosis of the arterioles with extreme cellular intimal thickening of larger interlobular and arcuate arteries and degenerative, proliferative, and slight exudative focal glomerular lesions. They believed that an ischemic mechanism is responsible for these changes, and they designated these cases as the accelerated atherosclerotic form. In the other form they observed necrotic lesions associated with perivascular inflammatory reaction, endarteritis and periarteritis. They recognized this latter form in two cases, in both cases a definite morbid process was present, recognized as toxic in origin. For such cases they used the term arteritic form of malignant nephrosclerosis. After carefully re-studying our material several times we failed to discover more than one case which would fulfil the requirement of the arteritic type. In this case there was a periarteriolar leucocytic infiltration with a proliferative endarteritis. We were unable to recognize an additional toxic factor either clinically or at autopsy. From the results of our observations we favor the view adopted by those who believe that no additional inflammatory influence is necessary for the development of the change seen in the so-called malignant stage. There are undoubted cases coming within the malignant class that represent the ef-

fects of a toxic arteriosclerotic combination. Such cases are described by Klemperer and Otani³³ and appear to be identical with Fahr's descriptions.

Attention must be directed to the fact that in group 3 (malignant), there are various degrees of arteriolar damage. Vascular lesions may range from the pre-necrotic stage characterized by advanced arteriolosclerosis with complete occlusion of the lumina of arterioles to an extensive arteriolonecrosis accompanied by peri-arteriolar and interstitial leucocytic reactions. Necrotic lesions of the arterioles may be sparsely scattered throughout the kidney being observed only after thorough search or by serial sections, or they may be so numerous that in every section many are seen. As shown in table 1 all patients that fulfill the requirements for a place in group 3 do not die of renal insufficiency. Those patients with the most fulminating form of renal failure dying of sudden onset of uremia had the most destructive forms of necrotic lesions in the kidney. Hypertrophy of the media of arterioles in skeletal muscles, and in internal organs has been emphasized by Kernohan, Anderson, and Keith³⁴ in cases of severe benign and malignant hypertension. They believed this hypertrophy of the media indicated a poor prognosis. Hypertrophy of the media in arterioles of skeletal muscles was present in some cases in group 2 as well as in all cases of group 3. With respect to hypertrophic changes in the media of renal arterioles there was more uncertainty. In some kidneys from both groups 1 and 2, moderate medial thickening was frequently seen. This thickening was found

not always to be hypertrophy of muscle tissue but due in places to degenerative changes in the media. We believe that medial hypertrophy may exist in arterioles of internal organs but it is not a constant feature of any group. On the other hand hypertrophy of the media in arterioles of skeletal muscle is a constant feature of group 3 and is associated with persistent and severe hypertension.

SUMMARY

1 Three hundred and seventy-five cases of essential hypertension are analyzed. On each of these postmortem examination was made.

2 The cases are divided for convenience of study into three stages: functional, arteriosclerotic, and arteriolonecrotic. The clinical signs and symptoms and the causes of death in each stage are considered.

3 Retinal changes were observed typical of the various stages.

4 Detailed postmortem pathological data, gross and microscopic, are

presented covering weight of hearts, size and structure of kidneys, arteriosclerosis, and necrosis of blood vessels of involved organs.

5 Unifying features of all stages are hypertension, cardiac hypertrophy, and arteriosclerosis. The chief complications are apoplexy, heart failure, and renal failure. Arteriosclerosis of the renal vessels is a constant and characteristic feature of essential hypertension at autopsy. Particular attention is given to the syndrome of so-called malignant hypertension.

6 Histologically the principal lesion is an arteriosclerosis. The wide variety of symptoms and signs appears to depend upon the extensiveness, the rate of progress, the severity, and the location of the arteriosclerosis.

7 The clinical and histological observations on group 3 (so-called malignant hypertension) differ from those in group 2 (benign) only in degree. All of the symptoms and histological lesions observed, we believe, may be produced by arteriosclerosis alone.

Hypertension*†

A Study of Two Hundred Two Cases Followed for an Average of Ten Years—With Remarks on Causes and Treatment.

By J M BLACKFORD, M D , F A C P , and J N WILKINSON, M D.,
Seattle, Washington

HYPERTENSION has been the subject of hundreds of articles and a considerable number of books during the last twenty years. Cardiovascular consultants and insurance companies have furnished most of that is written on end results.

Actuarial experience gives an extremely gloomy picture of the outlook for hypertension. Insurance records are based, however, on approximately 90 per cent males and exclude, for manifest reasons, all hypertension cases discovered at the time of examination. Cardiovascular consultants see chiefly cases who are sick with circulatory disturbances and hence see a more or less selected group of patients. We have been able to find no follow-up studies on unselected hypertension cases.

Two years ago we reported a series of cases obtained by reviewing 10,000 consecutive histories of general examinations made before 1925. We took for study all cases whose blood pressure was found definitely high,

using cases in which the systolic pressure was reported as 175 plus or the diastolic pressure 100 plus. Cases with readings below these figures were omitted because there is some question to whether temporary causes, particularly nervous, may occasionally give a reading up to these points. Thus we obtained a consecutive series of hypertension cases, unselected except by the fact that some complaint made them come in for a general examination.

Our clinic sees in each decade approximately an equal number of men and women, yet hypertension was found twice as frequently in women (64 per cent) as in men (36 per cent). In each decade between 30 and 70 years the percentage incidence of hypertension in women was approximately double that seen in men. Yet more than half of the women were without hypertensive symptoms, whereas hypertension in men was usually accompanied by symptoms. The large symptomless group of females with hypertension is not seen in cardiovascular clinics or by life insurance companies, and hence is not included in hypertensive follow-up studies.

*From the Mason Clinic, Seattle, Washington.

†Presented at the San Francisco Meeting of the American College of Physicians, April 6, 1932.

FOLLOW-UP STUDY

A follow-up study made two years ago gave information on the condition of 202 patients after an average of eight years. One-half (50 per cent) were dead. The female mortality was 42 per cent, whereas the male mortality was 79 per cent. About three-quarters of all deaths resulted from hypertensive disease, usually failure of heart or of cerebral circulation and occasionally nephritis. One-quarter of all deaths resulted from other causes.

We have followed 101 patients living two years ago down to the present. The gross mortality now is 60 per cent, but female mortality is 50 per cent and male mortality is 82 per cent, after an average of ten years. No male with marked hypertension still survives. Of 66 females surviving, 39 (59 per cent) are relatively symptom free, whereas of 13 surviving males 3 (24 per cent)

are relatively symptom free. Seven females are still alive in spite of marked or extreme hypertension discovered ten years ago.

Only two instances of recovery of a normal blood pressure have been noted.

These laborious follow-up studies and study of clinical histories have led to much reflection on the causes and treatment of hypertension.

CAUSES OF HYPERTENSION

Experimental hypertension has been produced by (1) various pressor substances, (2) removal of depressor nerves, (3) diffusely increasing intracranial pressure, and (4) experimental renal lesions which partially obstruct renal circulation. It should be noted that these experimental methods work through the sympathetic nervous system.

FIG 1

FIG 2

Clinical hypertension has been variously classified. The classification that seems to us reasonably complete is

- 1 Physiologic
- 2 Circulatory defects
- 3 Paroxysmal hypertension
- 4 Toxic
- 5 Renal
- 6 Neurogenous vasospasm

The last three groups include nearly all cases of clinical hypertension, and it is with these that we are here concerned.

Toxic hypertension includes cases due to known toxins which affect the kidneys, such as lead, mercury, and the toxins of the eclamptic state. Anaphylactic hypertension must be included here as well as the hypertension due to the toxic goiter. Hypertension due solely to toxic goiter is never high,

rarely as high as 175 mm, and is relieved by thyroidectomy. Higher readings than these in toxic goiter cases are not relieved by thyroidectomy, being due to essential hypertension associated with, but not due to, thyrotoxicosis.

Renal hypertension is found with chronic interstitial nephritis, chronic urinary obstruction, and often with polycystic kidney disease. It would seem that, as with experimental renal hypertension, chronic lesions offering obstruction to renal circulation are accompanied by hypertension of a compensatory nature. When such chronic obstruction can be relieved (as with prostatic cases) a normal blood pressure will be restored if there is not too much renal damage. Apparently there is a defensive compensatory angio-

spasm which automatically raises blood pressure as necessary to give an adequate renal circulation

Increasing intracranial pressure likewise automatically raises blood pressure sufficiently to maintain a cerebral circulation. Cushing's experiments have shown that when intracranial pressure is raised the blood pressure shows a corresponding rise.

We see, then, that the cerebral and the renal circulations, necessary to life, are preserved by a rise in blood pressure to compensate for chronic partial circulatory obstruction in these organs, and the rise persists during the period of obstruction. Chronic partial obstruction of the cerebral circulation by increased intracranial pressure results in early deaths unless relieved. In the renal circulation such chronic obstruction may exist for months or years, with increasing blood pressure to

compensate for increasing renal damage.

Essential hypertension brings us to a group of cases in which the blood pressure is high, without evident pathology to account for it. By far the greatest number of cases of hypertension fall into this group. It would seem that some constitutional tendency in the vegetative nervous system is responsible for the condition rather than unrecognized gross or microscopic lesions or retention of toxins. We recognize a hypotensive group of people, who may live long lives because lack of nervous endurance makes it impossible for them to wear out physically. We should recognize a hypertensive group, in whom the constitutional tendencies of the vegetative nervous system lead to generalized angiospasm with resulting hypertension. Early in this state of affairs there are no clinical symp-

FIG 3

toms and the patient may appear quite normal. Later, depending on the resistance of the vital organs and the arteries to stress, we see progressive wear on heart and vessels. Results of such hypertonicity of the neuro-vascular control of spasm vary from the early and acute breakdown, with arteriolar necrosis, of malignant hypertension in youth to the chronic myocardial and vascular degeneration of increasing age. In certain instances the patient may even reach a ripe old age relatively free from symptoms in spite of an extreme hypertension.

It has been stated that hypertensive disease runs in families. We have found a family history suggestive of hypertensive disease in more than one-third of all cases of hypertension, but approximately the same percentage of hypertension in family histories is found in all family histories of patients, regardless of complaints. In spite of these facts, most physicians feel that there is a strong family tendency toward hypertension in certain instances.

Available clinical and laboratory evidence suggests that hypertension must be regarded as the result of a generalized angiospastic state, a constitutional vascular hypertonus inherent in the individual. It rarely becomes evident before 40 years of age. It is far more serious in younger people. It is less serious but more frequently found in women than in men.

TREATMENT

Treatment based upon this conception becomes a matter of relief of stress, particularly mental stress, and of moderation of habits. Medical

treatment is reserved for relief of complications, and these may not develop for many years. Cardiac failure is the usual symptom that requires relief, with cerebral vascular symptoms next most common. Sedatives, both mental and physical, are required, with all the reassurances and encouragement that can be given. Bromides, barbitol derivatives, etc. are of great help.

Venesection is frequently indicated for relief of symptoms, particularly headache. The blood pressure is reduced only transiently by this procedure, yet subjective relief may last over weeks or months. Nitrites are occasionally valuable in relieving hypertensive headaches.

Weight reduction is always advisable in the obese. We usually prescribe a well balanced diet, low in salt and in proteid foods. Every effort should be made to avoid any dietary insufficiency leading to unnecessary anemia and loss of strength; and this can easily happen if the conscientious patient is advised to eat no meat or eggs.

Attempts at specific medication are always interesting. Aylen of Boston has found no drug of greater value than could be accounted for on a psychotherapeutic basis. To enumerate drugs recommended would make a long list. We may mention watermelon seed, mistletoe, liver extract, potassium sulphocyanate, and bismuth subnitrate as recent suggestions that have not stood the test of therapeutic practice. Possibly some day some specific remedy may be discovered. It seems to us doubtful if we can change constitutional tendencies inherent in the patient, even though we may greatly

relieve symptoms which result from the continuation of these tendencies

Fear, anxiety, and introspection are the most troublesome symptoms associated with hypertension. Unfortunately they are sometimes implanted and fostered by the physician. Fear of the consequences of hypertension causes more suffering for many patients than do all the later severe complications which may occur.

SUMMARY

In conclusion, we find that

1 Hypertension is twice as frequently found in women

2 The mortality rate after ten years is twice greater in men

3 Hypertension results from a constitutional hypertonicity of the autonomic neurovascular control in the large majority of instances and is a compensatory angiospasm in the others

4 Treatment of uncomplicated hypertension is a matter of mental and physical hygiene rather than of drugs

5 Treatment of late results of hypertension requires skillful use of medical and physical measures, added to psychotherapeutic measures

6 The physician who is a good and cheerful psychologist will be the most successful in relieving the symptoms of hypertensive cardiovascular disease

Thallium Poisoning

A Report of Three Cases*

By JAMES LEHMAN, M D , and LEO GARFNEY, M D , *Cleveland, Ohio*

THE increasing incidence of thallium poisoning, following the use of depilatory creams has prompted us to report the following cases which have been under observation recently at the Cleveland Clinic. In all three cases the history included a similar statement, namely, that the patient had used "Koremlu", a depilatory cream.

Several cases of thallium poisoning have been reported. Lansbury¹ of the Mayo Clinic reported the first case. A short time later, Duncan and Crosby² of the Cleveland Clinic reported a similar case. Greenbaum and Shamberg³ have also reported cases. The Bureau of Investigation of the American Medical Association has published a report¹ on the chemical analysis of "Koremlu", and branded it a dangerous depilatory, containing seven per cent of thallium acetate. Sabouraud, after an extensive experience with the use of thallium as a depilatory is said to have given up its use. (See Paris Letter, Jr Am Med Assoc, Jan 18, 1930.) Moreover, Sabouraud's original preparation called for an ointment with not more than one per cent of thallium acetate and the use of the oint-

ment in quantities not larger than the size of two kernels of wheat, to be applied not more than twice a day. In the directions for the use of "Koremlu", no mention is made of the amount to be used, nor the frequency of its application.

CASE I

A woman, 39 years of age, came to the Clinic on March 26, 1931, complaining of pain in both legs. She had been well until two weeks previous to her visit to the Clinic, when she noticed numbness and tingling in her toes. This progressed gradually until the entire lower extremities were involved. Two days before her admission to the Clinic the numbness was replaced by pain which was most severe in the knees and ankles, and it was necessary for the patient to remain in bed. The pain was confined to the lower extremities and was relieved somewhat by the application of heat.

The family and personal history had no bearing upon the existing condition.

The significant findings in the physical examination were the following: the hair was well nourished and was distributed normally, except for hypertrichosis of the face. The tonsils, which were of moderate size, were imbedded and contained debris and liquid pus. A complete x-ray examination of the teeth showed one carious tooth, periapical infection about the first and second premolars of the upper left, first and second premolars of the upper right, first molar of the lower left and second molar of the lower right jaw. The patient was advised to have these teeth extracted. The tongue was heavily coated, and a slight

*From the Cleveland Clinic, Cleveland, Ohio. Submitted for publication, November 12, 1931.

tremor was present. A special neurological examination by Dr W James Gardner gave the following positive findings: pain, deep tenderness and muscular weakness of both lower extremities, moderate hyperesthesia of the skin with no definite level, diminished plantar, patellar, Achilles and triceps reflexes.

The patient was admitted to the Cleveland Clinic Hospital with a diagnosis of toxic neuritis, carious teeth, and chronic tonsillitis. Further questioning of the patient brought out the fact that she had been using a depilatory cream, "Koremilu", applying it twice a day. We felt justified, therefore, in making a diagnosis of peripheral neuritis, due to the toxic effects of thallium absorbed from the depilatory cream.

TREATMENT

During her stay in the hospital, the patient was put at absolute bed rest and external heat was applied to the lower extremities. Passive motion and massage were instituted. She was also given an alkaline diuretic. The six diseased teeth and the tonsils were removed. On April 8, 1931, the patient was discharged somewhat improved.

On April 29 she reported that all pains had disappeared with the exception of some discomfort in the legs when fatigued. There was still a sensation of numbness in all the toes. Fatigue was marked, but there was good power in the dorsi-flexors.

The latest report from the patient was on July 22 when she stated that she was free from pain except for a slight prickling

FIG 1 Marked alopecia after using "Koremilu Cream" for removal of hair from the face

sensation or partial numbness after walking rapidly or great distances. For a month past she had noticed that her hair had been falling out.

CASE II

A woman, 28 years of age, was admitted to the Cleveland Clinic Hospital on April 21, 1931, complaining of aching pain in the thighs and legs, impairment of sensation in legs, arms, feet and hands, abdominal cramps not associated with nausea or vomiting, generalized weakness, inability to walk, loss of cranial, axillary and pubic hair, speech impairment, menstrual irregularity, restlessness, irritability and insomnia.

The patient was well until three and one-half months previous to her admission to the hospital. The symptoms were noticed from two to three weeks after she had started using "Koremnu" cream for the removal of hair from the face. This cream was purchased from a department store in Akron, Ohio, at a cost of \$10.00 for a small jar. The patient had been applying the cream once a day until she came to the hospital.

The first symptom noticed was the aching pain in the legs, especially in the calf muscles. After about a month she noticed that she was losing the power of her legs which became complete three weeks previous to her admission to the Clinic. Following this, abdominal cramps developed, which gradually increased in severity. There was no nausea, vomiting or diarrhea on taking of food. About six weeks after she started using the cream, her cranial, pubic and axillary hair began to fall out until almost complete alopecia resulted. The hair on the face was not affected. Generalized weakness gradually developed including impairment of sensation in the legs, arms, hands, and feet, the menstrual flow became very scant, the patient became restless and could not sleep. She had lost about five pounds.

The significant findings in the physical examination were as follows. The skin was rather dry and smooth, there was very little hair on the arms or legs and the loss of cranial hair was marked, the scalp was dry and scaly, the hair was dry and easily

pulled out. The eyebrows showed loss and what remained were easily pulled out. The tongue was coated and rather dry. The tonsils which were of moderate size contained debris and some infectious material. The abdomen was slightly tender just below and to the left of the umbilicus but no masses were found and there was no rigidity.

Marked tenderness was present over the posterior aspect of the thighs, and over the anterior and lateral portions of the legs, there was suggestive impairment of sensation over the inner aspect of the right leg, the muscles, especially of the thighs and legs, were flabby. The patellar and biceps reflexes were fairly active and equal, there was some numbness and tingling in the legs, feet and hands. Loss of motor power in the legs and arms was noted and the patient could stand for a few minutes only.

Dental examination revealed no devitalized teeth and no evidence of periapical infection; there were two extensive restorations, and the patient was advised to have these teeth tested for vitality, and to have them extracted if necessary.

Neurological examination revealed impaired gait, toe drop, bilateral partial paralysis of the lower extremities, bilateral atrophy and hypotonicity of the lower extremities, paresthesias of the legs and hands and impairment of sensation of the legs. The patient's voice was husky and she was mentally depressed.

About a week before her admission to the hospital the patient refused to have an exploratory laparotomy in order to determine the cause of the abdominal cramps.

Treatment

The patient was given 3500 c.c. of fluid over a twenty-four hour period. Sedatives were administered as indicated for pain or insomnia. A cradle was placed over the lower extremities to protect them from the weight of the bed clothes, and the soles of the feet were supported to overcome the footdrop. Calcium chloride was administered intravenously in doses of 20 c.c. of a five per cent solution every second day. After five injections, the symptoms became worse and this treatment was discontinued.

Heat, light and massage were applied to the lower extremities

When the patient was discharged after twenty days, her condition was slightly improved. The hair was still falling out but the pain in the extremities was less severe and the abdominal cramps were not so constant. The patient was less restless and slept better. She was still unable to walk, however, and the leg muscles showed increasing wasting. Bilateral toe drop and positive Babinski were still present and the reflexes were still diminished. Numbness and tingling were still present in the hands and feet. The general condition of the patient was somewhat improved, however, and she was less depressed.

A report from the patient's physician on July 7 stated that she had shown slight improvement since her return home but was still confined to her bed and unable to walk. Pain was still present in the legs but the abdominal cramps had disappeared. The leg muscles showed a moderate degree of wasting. The cranial hair had begun to grow and was about one and one-half inches long. The patient was receiving massage

and passive motion of the legs daily. She still required sedatives occasionally.

CASE III

A woman, 27 years of age, came to the Clinic on July 8, 1931, complaining of pains in the legs. The pain began about August 30, 1930, three weeks after she began using "Koremlu Cream" for the removal of hair from the face. In spite of the fact that the pain became worse as the patient continued to use the depilatory, she did not and had not to date connected the use of the cream with the pains, which she described as being dull and aching and made worse by motion. After two months the pain became so severe and constant that she was confined to bed. Her family doctor could not find the cause of the trouble and his treatment gave no relief. He finally sent her to a hospital in Pittsburgh, where a thorough study was made of the case. Just before going to the hospital, she began having cramplike pain in the abdomen. A gastro-intestinal series was done but no pathological condition was demonstrated. While in the hospital she stopped using the

FIG 2 Foot drop and muscular atrophy of lower extremities in thallium poisoning

cream and at the end of three weeks she felt somewhat improved and was discharged. After she returned home she began using the cream again and the pain in the legs and abdomen returned. Associated with the pains at this time was a marked sensitiveness of the feet, which prevented walking.

After trying various treatments for two months she decided to go to Hot Springs, Arkansas, to take the baths. A few days after arriving there she finished her second jar of "Koremlu Cream" and was unable to buy any at Hot Springs. She took a series of baths and her health began to improve. She remained at the Springs for about four weeks. At the end of that time, nearly all the pain was gone and she was able to walk without any discomfort. The patient returned home and enjoyed freedom from pain for two months, during which time she was not using the cream. A short time later she bought another jar and began using it each night, and continued to use it up to the time of her admission to the Clinic. About three weeks later, the pain in the

legs, and sensitiveness in the feet and the cramps in the abdomen returned. The patient mentioned to several doctors that she was using "Koremlu Cream" but they all assured her that this could not be the cause of her trouble. She had had no loss of axillary, axillary or pubic hair.

Examination at the Clinic showed a well nourished woman, not actually ill. The only positive physical findings were atrophy of the left calf and thigh, to the extent of about one and one-half inches, and tenderness along the course of the nerves of the legs. No attempt was made to isolate thallium from the urine.

In view of the fact that the pain first occurred shortly after the patient started using the "Koremlu Cream" and because the pain disappeared when on two occasions she discontinued the use of the depilatory, we felt that we were justified in making a diagnosis of chronic thallium poisoning. The patient was advised to discontinue the use of the cream and to have light massage and light treatment for the legs.

Newer Aspects in Parodontosis (Pyorrhea)*

By HERMANN BECKS, M D , D D S , *San Francisco, California*

OUR conceptions of the true anatomic conditions in the region of the tooth supporting tissues or "paradentium" (Weski) have recently undergone a definite change through the work of contemporary histologists and clinicians (Boenheim, Citron, Gottlieb, Haupl, Lang, Loos Weinmann, Weski)

This change in our ideas brought about a renewed interest in the etiologic and pathogenetic questions in parodontosis in all countries. Today after twelve years have elapsed there are still questions of fundamental importance which are under debate, the solution of which may not be reached in any short space of time. These are mainly histologic details which, however, are of immense importance to the practicing dentist; these he must know in order to be able to understand the etiology, pathogenesis, and therapy of the disease. Before these new conceptions can be adopted it will be necessary to throw overboard many antiquated theories, otherwise we will become involved in a maze of complicated ideas, from which it will be very difficult to extricate ourselves.

One of the greatest advances in the last few years in this particular field

*Presented at the San Francisco Meeting of the American College of Physicians April 5, 1932

has been in the new terminology which was decided upon by vote of the Eighth International Dental Congress, at Paris, in August, 1931. I refer to the term "parodontosis", which replaces the old term "pyorrhea".

A classification has been adopted which includes all known types of the disease formerly called "alveolar pyorrhea", "periodontoclasia", etc. It groups all cases according to their clinical symptoms. The designations, as such, have been chosen to point to the pathogenesis of the disease.

CLASSIFICATION

- 1 Marginal suppurative gingivitis
Local manifestations
Superficial inflammation with discharge of pus at the gingival margin
Calculus
No distinct pocket formation
- 2 Parodontosis
 - a. Profound simple parodontitis
Local manifestations
Deep pocket
Pus
No loosening of the teeth
 - b. Diffuse dystrophy
Local manifestations
Irregular atrophy
Migration or loosening of teeth
No pus

c Complicated dystrophic paradentitis

Local manifestations.

Deep pocket

Pus

Eventual loosening of teeth or migration or both

The final phase of a, b, and c, is:

Loosening of teeth, deep pockets, pus

3 Alveolar atrophy

a Pre-senile atrophy (*atrophia praecox*)

Local manifestations

Early recession of the gingival margin

Horizontal atrophy of bone

b Senile atrophy

Local manifestations

The same as under "a", but at an advanced age

It is of especial importance to observe that in this classification the marginal suppurative gingivitis, which was formerly designated as "pyorrhea", has been separated from the large group of parodontosis. This has been done because such a marginal suppurative gingivitis with a slight discharge of pus exists over a period of years without developing into a parodontosis; i.e., without involving the deeper parts of the parodontium. Of course this condition may suddenly become an ulcerative type of gingivitis or paradentitis, which in the course of time involves the bone and leads to the clinical picture of parodontosis.

On the other hand the alveolar atrophy has also been separated from parodontosis because it represents a special group of diseases.

Parodontosis itself is subdivided into three main groups, which include all

types of this disease of the parodontium known at the present time. However, it may be emphasized that this classification is only tentative and has been adopted in order that practitioners of medicine and dentistry, as well as research workers, may be provided with a uniform working basis. Doubtless, it would be easier for the practitioner if a classification could be made which includes the etiological factors, i.e., if we could speak of a diabetic parodontosis, of a scorbutic or an arthritic parodontosis. However, our research has not progressed that far as yet.

There is a very definite conception of the disease connected with this new designation, which means more than just "pyorrhea", which is defined as "pus discharge from the gum pocket". We must try more than ever to forget the symptom of pus in establishing the diagnosis, since this does not indicate the condition of the tissues. Our observations should be directed toward the morphological and clinical changes to be treated and here we must be interested first in the factors which have led to these changes in the parodontium.

The parodontosis problem is a part of a constitutional problem. The *individual disposition* forms the nucleus of the susceptibility to parodontosis, which on the one side occurs as a result of systemic disease and on the other on the same basis as the disease itself. We speak of endogenous factors in collusion with well known exogenous factors, by means of which the parodontosis has gained a foothold. At the present time we have very little scientific information about these en-

ogenous factors, which influence the occurrence of paradentosis

In the etiology we differentiate today between two fundamental forms of paradentosis. First, that which is characterized by an inflammatory disappearance of marginal tissue, and second, one with a generalized tissue destruction. Although we have gained a vast amount of knowledge concerning the first type in etiologic and histopathogenic respects, there still exists a great hiatus in our knowledge of the etiology of the genuine type, which seems to be based on an abnormal condition in bone apposition and resorption, i.e., a lack of stability in bone metabolism (Loos, Weski). Several times Loos has expressed the opinion that this form of paradentosis, which is based on the instability of the bone metabolism, occurs as a result of an osteopathy with an endocrine genesis. We have not advanced beyond this point as yet and only recently in our laboratory at Hooper Foundation we were able to furnish for the first time the scientific proof of this theory by means of diet experiments in animals.

We will omit from the following discussion the marginal suppurative gingivitis, which is caused essentially by exogenous or local factors and concern ourselves only with that form of paradentosis which cannot be explained by local irritation only and must, therefore, fall in the field of investigation of the general system. We do not know definitely whether or not a special constitution of the capillary system of the parodontium or of the osseous system (Loos) brings about a susceptibility to the disease. However, we may accept this as an hypoth-

esis. At the present time, in all countries, workers are feverishly active in the endeavor to establish a relation between paradentosis and diseases of metabolism, diseases of the blood-forming organs, hormonal disturbances, and disturbances of the vegetative nervous system. Even though they have not become pathognomonic for paradentosis as yet, all investigations and examinations in this direction are extremely important for paradentosis as a medical problem.

If we start with the supposition, as already mentioned, that the osseous part of the parodontium primarily gives a constitutional basis for paradentosis or that through other endogenous factors the alveolar process undergoes changes which lead to the typical atrophic and dystrophic symptoms, an especially interesting field of investigation is that of calcium metabolism.

In the year 1929, I reported that the electrolytic content of the saliva in patients suffering from the so-called diffuse atrophy deviated from the normal. This was of importance because no studies in mineral metabolism had as yet been made. At that time I reported that in the saliva of seventeen cases of diffuse atrophy of the alveolar process the potassium and sodium contents were increased and the calcium and phosphorus contents were decreased as much as 25 per cent. At the same time a publication of Citron appeared covering the examination of serum calcium in patients with paradentosis and a few others along this same line followed (Kauschansky, Herz, Weinmann, Becks). Citron examined eighty-seven cases of para-

dentosis, which had not been classified exactly, for serum calcium and potassium. He also examined the basal metabolism, the specific dynamic action of foods, and microscopically the capillaries of the gum tissue. In these patients all laboratory findings showed some metabolic disturbance. Citron related these disturbances to a primary dysfunction of the glands of internal secretion. He classified them as thyroid, parathyroid, ovarian, and pituitary types of paradentosis and believed that they were a symptom of a general systemic disease. In these eighty-seven cases he found that the serum calcium value was between 8 and 9 mg. per cent in three cases, between 10 and 12 mg. per cent in seventy-three cases, and between 13 and 17 mg. per cent in eleven cases. This means that in the majority of cases suffering from paradentosis, the serum calcium content was increased.

Weinmann, one of the most enthusiastic supporters of the so-called diffuse atrophy as an independent disease, which is designated in the new classification as diffuse dystrophic type of paradentosis, found approximately the same percentages, while Herz found normal calcium values in most of his cases. Kauschansky found calcium values above 11 mg. per cent in 35 per cent of his cases (he examined 135 patients with "alveolar pyorrhea").

The weakest point in these publications is that the cases of "alveolar pyorrhea" were not classified. Frequently in scientific publications we find the same confusion that is prevalent among practitioners, i.e., a lack of the exact details of diagnosis. Weinmann is the only one who made

examinations exclusively of cases with diffuse dystrophic paradentosis, while a mixed material was used by other investigators, which may be composed to a large extent of cases of simple gingivitis, designated today as marginal suppurative gingivitis, and naturally in these cases we cannot expect to find any change in calcium metabolism. The conclusions which were drawn from these findings are, therefore, without value.

The cases of paradentosis which I have examined within the last year have been grouped according to the new classification. Only cases of the diffuse dystrophic type were examined; i.e., cases of Gottlieb's diffuse atrophy. These were cases which roentgenologically showed extreme resorption of the alveolar process. The patients were young adults between the ages of twenty and thirty-five years. The resorption was too far advanced to be accounted for by the age of the patient and the degree of inflammation present. There existed a tendency to migration and slight loosening with pocket formation.

The majority of cases—there were only a very few exceptions—showed *an increase of the amount of serum calcium*, i.e., we confirmed the statements of Citron, Weinmann, and Kauschansky. The serum calcium values reached as high as 18.15 mg. per cent. The cause of this increase in the amount of serum calcium is still problematic. Citron believes that the hypercalcemia must be traced to an increased function of the parathyroids. He bases his conception on the fact that an elimination of the parathyroid function leads to an increase of

potassium and to a decrease of the calcium in the blood while the reverse condition would mean an *over-function* of the gland. Experimentally this has been proven by the administration of large doses of Collip's parathormone.

The potassium-calcium quotient of normal cases gives a practical index which can be used in determining an unbalanced condition. If the normal potassium content is about 20 mg per cent and the normal calcium value lies between 9 and 11 mg per cent, the potassium-calcium quotient is about 1.6 to 2.0.

In the thirty-seven examinations of Weinmann, in which he found hypercalcemia twenty-seven times, the potassium-calcium quotient was below normal only eight times, while it was above seven times. This vacillation of the quotient, of course, does not allow any conclusions concerning the participation of the parathyroids in this process. Weinmann even expresses doubt that the increase in serum calcium may be traced back to a mobilization of calcium salts from the bone.

In our examinations, we found that the serum potassium value was just as frequently increased as decreased. *However, the striking fact was established that in the twenty-four cases examined, eleven cases showed a low, four a high, and nine a normal potassium-calcium quotient.* This seems to show that the increase in blood serum calcium parallels a relatively low potassium value, which led in the majority of cases to the low potassium-calcium quotient. On the other hand a relation to an endocrine disturbance seemed to exist in our cases, which is in contrast to the findings of Weinmann.

The porotic jaws which we observe so very frequently in roentgenograms suggest that a disturbance in the balance of bone apposition and resorption may be present. Whether this disturbance is produced by the endocrine system, by a deficient diet, or constitutional anomalies is rather a secondary question. First, it must be proven scientifically that such a disturbance really exists and for this purpose the calcium analyses of the blood serum alone are of no value whatsoever. As already shown, they can be used in connection with potassium analyses and may help explain the participation of the endocrine system. However, in order to be able to draw conclusions concerning the participation of the osseous system we must consider other factors. Of these I might mention the phosphorus metabolism in its relation to calcium metabolism, further, the carbon dioxide capacity of blood, the basal metabolism, and the specific dynamic action of proteins.

From the investigations of Dr. E. V. McCollum and his co-workers, we know that the growth of the osseous system depends on the vitamin D content of the food and the correct calcium-phosphorus ratio. If this is undisturbed, i.e., no relative excess of one or the other, a comparatively small amount of vitamin D is sufficient to guarantee good calcification of the osseous system. However, if there is an excess of one or the other, small quantities of vitamin D do not suffice to prevent severe disturbances of calcification. In other words if the calcium-phosphorus ratio is disturbed an abundance of vitamin D must be given in order to compensate for the im-

balanced ratio. Otherwise the typical picture of rickets results.

If we consider in this connection the osseous system of an adult for some time on an unbalanced diet, which for instance did not contain calcium enough in proportion to phosphorus, osteoporotic changes develop which manifest themselves in the jaws by a destruction of the trabeculae and an enlargement of the marrow spaces. The same osteoporotic changes of the alveolar process are found if a growing dog is fed with a basal diet and a normal salt mixture, but without the addition of cod liver oil (vitamin D). Roentgenograms show the jaws of such animals to be less dense than those of animals receiving sufficient vitamin D.

If we omit a large part of the calcium in the diet, as well as vitamin D, the typical picture of diffuse *dystrophic* paradentosis develops instead of an osteoporosis. We find typical horizontal and vertical types of atrophy, as well as periodontal dystrophy. These lead clinically to a loosening of the teeth with a tendency to migration, which is especially marked in the region of the anteriors.

The calcium metabolism, therefore, bears a very close relation to the vitamin D content of the food. On the other hand, we know that the calcium metabolism is regulated and controlled by the endocrine system, especially by the parathyroids. According to our experiments, vitamin D represents in a certain way a mediator between the calcium metabolism and the endocrine system. If the osseous system in these cases of paradentosis is primarily involved to a certain extent—which we must believe from our experiments—

the question arises in what way the calcium-phosphorus metabolism is changed.

In our blood serum analyses of patients suffering from diffuse dystrophic paradentosis we found an *increased amount of calcium*, as already mentioned. The inorganic phosphorus content is decreased in 50 per cent of the cases and in others it is normal. The calcium-phosphorus quotient, which lies for normal serum between 2.4 and 3.0, is increased in about 50 per cent (of the 25 cases examined).

The examination of the saliva revealed in about 90 per cent of these cases a *decreased calcium amount* with normal or slightly increased phosphorus values. This results in a low calcium-phosphorus quotient, this is exactly the reverse of what we found in the blood. We see, therefore, that we are dealing with a definite disturbance in the potassium-calcium and the calcium-phosphorus quotient in these cases of paradentosis.

Clinically we observe that bone substance is being lost and biochemically we find a hypercalcemia with a frequent relative or absolute lack of phosphorus in the blood serum.

In the mixed resting saliva, however, we find a hypocalcemia and a normal or relatively high phosphorus content.

These findings have carried us one step further in the recognition of these types of paradentosis. They may be interpreted to mean that either an endocrine disturbance, perhaps pluri-glandular disturbances, a deficient diet, infectious disease, or other metabolic diseases mobilize calcium salts from the bone and perhaps from the teeth,

which leads to an increase in the amount of calcium in blood serum. This increase of serum calcium in most of the cases is not accompanied by an increase of the blood phosphorus resulting in a relatively high calcium-phosphorus quotient and a low potassium-calcium quotient. Since we find in the mixed saliva of these patients a low calcium content with a relatively high phosphorus content, which is exactly the opposite of what we find in the blood, we must trace this to the factors influencing the secretion or excretion processes in hypercalcemia.

This shifting in the calcium-phosphorus quotient encourages me to define more precisely that type of paradentosis with which the medical

and dental professions are so often confronted. *The diffuse dystrophic paradentosis* is characterized clinically by a primary bone disturbance on the basis of an osteopathy with a tendency of the teeth to migration and loosening without inflammatory symptoms. This osteopathy is so slight that no clinical manifestations of disturbance of the general osseous system are to be found. The biochemical aspect is characterized by a high calcium-phosphorus ratio of the blood serum. The total serum calcium amount is increased with a relative or absolute lack of inorganic phosphorus. The potassium-calcium ratio of blood serum is frequently found below normal.

The Report of a Case of Early Hodgkin's Disease Secondarily Infected with a Strain of Pathogenic Monilia *

By SAMUEL R. HAYTHORN, M D , F A C P., GEORGE H ROBINSON, Ph D , and
LLOYD JOHNSON, M D , *Pittsburgh, Pa*

THE patient concerned in this report was a man 70 years of age who presented an unusual combination of clinical and pathological findings. The diagnosis of Hodgkin's disease was based entirely on the microscopic changes and was not suspected during life or from the gross findings at autopsy. The outstanding features of the case were inflammatory lesions of the lungs and spleen and the isolation of a pathogenic strain of monilia. The unusual lung lesions were found microscopically to be nodules of organizing pneumonia through which numerous large cells of the "Dorothy Reed" type were distributed, and which we interpreted as having been attracted to the site by the irritating influences of the monilia. There were several other unusual circumstances not commonly associated with Hodgkin's disease such as the age of the patient, the atypical blood picture, the absence of enlarged glands and the unusually high fluctuations of the temperature.

*From the William H Singer Memorial Research Laboratory and the Allegheny General Hospital, Pittsburgh, Pa. Received for publication, September 18, 1931.

CASE REPORT

Abstract of Clinical History *First Admission*

Mr W A N, aged 70 years, a farmer, was admitted to the service of Dr Lloyd W Johnson on August 15, 1928. There was no family history of neoplasms and the patient's habits were of the best. He was an active farmer, working from twelve to fourteen hours daily until one week before his first admission and then complained chiefly of chronic arthritis.

He was admitted for chills, fever and arthritis. No satisfactory diagnosis was made and he was discharged in two weeks, much improved. All examinations were negative. There were no enlarged glands.

Second Admission

He returned October 2, 1928, with chills and fever, pain in gall-bladder region and arthritis. The fever alternated with chills and the temperature rose daily to 101° or 103°, the pulse going to 110 or more. Toward the last the daily temperature curve was typical of septicemia.

Physical examination showed pyorrhea, a heavy coating of tongue, and slight jaundice. The glands still were not enlarged. Six weeks before death the patient began to cough. Crackling râles were present in the lungs. Ten days before death a definite bronchopneumonia developed. The pain in the upper abdomen was almost unbearable. The patient died December 14, 1928.

The treatment throughout was symptomatic. Several blood transfusions were

made Potassium iodide was given for four weeks without improvement

Blood examination on the second admission (10-2-28) showed red blood cells, 3,170,000, white bloods cells, 11,000, hemoglobin, 80%, Sahl's, polymorphonuclears, 75%, lymphocytes, 22%, large mononuclears, 3%

The final blood examination, made on 12-5-28, gave red blood cells, 2,900,000, white blood cells, 14,500, hemoglobin, 64%, polymorphonuclears, 86.5%, lymphocytes, 9%, large mononuclears, 4.5%, eosinophiles, 0, in 200 cells

The urine was negative The icterus in-

dex, 36 units bilirubin The Widal test, *B abortus* and *B tularensis* agglutinations were negative The Wassermann and Kahn tests were negative. The sputum was negative for tubercle bacilli

The X-ray verified the arthritis and diffuse infiltration of the lungs

Clinical Diagnoses Chronic cholecystitis, arthritis, septicemia due to undetermined cause, icterus, terminal bronchopneumonia and myocarditis

Abstract of Protocol

The body was that of an emaciated male 170 cm in length The skin and sclerae

FIG 1 Left lung showing Hodgkin's disease nodules and diffuse organizing pneumonia near base

were distinctly yellow. All of the upper teeth and several of the lower ones were absent. Those remaining were in poor condition. The tongue was heavily furred. There were no skin lesions and no superficial glandular enlargements.

Pericardium The pericardial sac contained 100 cc of bloody fluid. A firm band of adhesions connected the apex of the heart to the parietal pericardium, and there was an area of acute fibrinous exudate on the epicardium.

Heart Weight 490 Gm. The cavities and valvular orifices were negative, the coronary arteries were sclerosed, one branch of the left coronary being completely obliterated. The myocardium was white and fibrous.

Left Lung Weight, 355 Gm. The upper lobe was not remarkable. In the lower lobe

there were two kinds of nodules, varying in size up to a diameter of 2 cm. Two of the larger ones appeared to be calcified tubercles. The other nodules were numerous and had no distinct borders. Some were firm, white and tinged with red. Others were hard, white, and had excavated centers containing a thick creamy exudate. The lung tissue between the nodules was dry, air containing, and appeared normal. The bronchi were moist, reddened and some contained muco-pus. The peribronchial lymph nodes were enlarged to about 2.5 cm in diameter, were grayish white in color, and resembled nodes infiltrated by tumor growth.

Right Lung Weight, 510 Gm. Nodules similar to those in the left lung were present in all three lobes. In the lower lobe was a small area of diffuse consolidation 5 by 3 by 2 cm, and scattered areas of

FIG 2 Smear from active culture of *monilia*, showing mycelial and budding forms
Oil immersion

bronchopneumonia There were also collapse of the posterior portion of the upper lobe and compensatory emphysema of the apex The bronchi and nodes resembled those of the left lung

Gastrointestinal tract There was an acute inflammation of the duodenum and edema of the papilla of Vater The rest of the gastrointestinal tract was negative

Liver Weight, 1590 Gm In general the liver presented the picture of chronic passive congestion with moderate bile stasis There were three firm white irregular nodules with sharply scalloped borders and reddened margins The largest was 2 cm. in diameter and had a cartilage-like center The gall bladder was distended with thick, sticky, mucoid, reddish-green bile The mucosa was injected, edematous and inflamed No stones were present

Spleen Weight, 295 Gm It measured

17 by 9 by 4.5 cm The capsule was thin and tightly stretched Pale blotches were apparent beneath it On section the pulp was a deep, purple color with many creamy white spots

Kidneys Both kidneys presented the picture of chronic arteriosclerotic nephritis with retention cysts The right contained a healing infarct near the upper pole

The mesenteric and retroperitoneal nodes were somewhat enlarged, white, firm, and infiltrated

The pancreas, adrenals, prostate, bladder, and testes were negative

The head was reserved The joints were not opened

Principal Diagnosis General granulomatosis of uncertain cause

Additional Diagnoses Acute fibrinous pericarditis with effusion, old pericarditis with adhesions, healed infarct of myocardium

FIG 3 Smear made from a mixture of *monilia* and blood The *monilia* take the nuclear stains The preparation shows the difficulty of differentiation between the fungal spores and the nuclei of the leukocytes The resemblance made the demonstration of *monilia* in tissues particularly difficult

um, collapse of right lung with compensatory emphysema, chronic adhesive pleuritis, healed tuberculosis, multiple infarcts of spleen with enlargement, chronic passive congestion of liver, chronic cholecystitis and cholangitis, chronic nephritis, adenomatous hyperplasia of the prostate, general icterus, enlargement of joints

Post Mortem Bacteriological Report

Cultures were made at autopsy from the heart blood, pericardial fluid, bile, spleen, lungs and peribronchial nodes. All cultures yielded a heavy growth of *B. coli*. Large organisms, apparently mycelial forms of a fungus, could be seen in the cultures from heart blood, spleen, pericardium and peribronchial lymph nodes. After two weeks' incubation the colon bacilli died out and the fungus which proved to be a strain of *monilia* was isolated in pure cultures.

The *monilia* colonies were white and glis-

tening. When less than 24 hours old short arboreal processes extended from the colony. On microscopic examination these processes consisted of branching mycelia with oval spores forming at the ends and nodes. Sections of older colonies revealed only spores with occasionally a shadowy or skeletal remnant of a mycelium. All forms were Gram positive and showed no structural features except an irregular concentration of the nuclear material in some of the spores.

In broth this organism grew with slight granular turbidity which generally settled to the bottom. Acid was produced in dextrose and maltose broth. Lactose, saccharose, mannite and salicin were not affected. It did not give the characteristic yeast odor in broth or upon potato.

Large doses of culture administered intravenously were fatal for rabbits. Subcutaneous inoculation in rabbits and guinea pigs produced abscesses.

FIG 4 Photograph to show *monilia* in lung nodule. Note the group of *monilia* just above the center of the field. These *monilia* stood out as red bodies with pyronin and light green.

Diagnosis Monilia (species not determined)

Microscopic Findings

Heart The myocardium showed fibrous myocarditis

Lungs The lung sections showed a diffuse purulent exudate throughout the bronchi and bronchioles. They contained many bacteria and some larger irregular forms resembling monilia. The large cells to be described in the nodules were also seen in the alveolar walls at some distance from the nodules. There were a few areas of organizing pneumonia not associated with nodules.

Several sections of the lung contained well defined nodules, which were discrete, situated beneath the pleura. The margins were sharp and without limiting membranes. The alveoli in the advancing margins of the nodules were filled with fibrinous exudate and were often found lying next to normal

air sacs. In the affected areas all structures including bronchioles, blood vessels and alveolar spaces were destroyed by the granulomatous process. Apparently the reaction consisted of a primary fibrinous exudate which spread at the borders and organized at the centers. A typical nodule included one or more small bronchioles in which the epithelium was partially thrown off and partially swollen and adherent. The bronchial submucosa was infiltrated with an exudate of polymorphonuclear leucocytes. Toward the centers of the nodules, all normal landmarks were lost and the mass was made up of interlacing strands of fibrin, newly formed fibroblasts, fibrils, capillaries, infiltrating cells and broken bits of monilia. The monilia were differentiated with difficulty. They were not acid fast. They stained blue with phloxine-methylene blue and with the Gram-Weigert method. In both instances they took the fibrin and

FIG 5 Photograph of lung showing bronchiole filled with leucocytes and alveoli filled with fibrin undergoing organization

nuclear stains and could not be differentiated with certainty. By means of Giemsa's stain they could be differentiated from fibrin but not from nuclear particles. At the suggestion of Dr. Baldwin Lucké, pyronin and light green were used and a moderate number of red staining bodies which were morphologically monilia were found distributed throughout the lung lesions and bronchioles.

The kinds and relative numbers of inflammatory cells in the nodules varied considerably from field to field. Polymorphonuclear cells were diffusely distributed. Lymphocytes, plasma cells and large mononuclear phagocytes were very common and were the predominating cells in some areas. Some of them contained phagocytosed ovoid monilia, often two or three to a cell. Typical phagocytic foreign body giant cells with from three to ten or more nuclei were numerous and widely distributed. The unusual feature was the presence of many large cells which appeared to be identical with the "Dorothy Reed" cell of Hodgkin's disease. These were large cells with pink cytoplasm, irregular borders, vacuolated nu-

clei, which often had multiple nucleoli. Some of the cells were in mitosis and some had more than one nucleus. Some of these cells resembled megakaryocytes of the bone marrow.

Liver In several sections there were portions of nodules, which were identical with those found in Hodgkin's disease.

Spleen In general the spleen showed congestion with areas of red cells. The white granulomatous areas were essentially infarcts, with borders which were not sharply defined. "Dorothy Reed" cells were numerous in the pulp. Golden pigment-bearing cells and foreign body giant cells completed the picture.

Kidneys A moderate degree of arteriosclerotic nephritis was present, and one section had an infarct in the later stages of healing. The sclerosis was of the Monckeberg type.

Lymph Nodes The lymph nodes were replaced by fibrous tissue and presented the usual picture of Hodgkin's disease. The lymph follicles and normal arrangement of the nodes were lost. In some parts the

FIG 6 Photograph of peribronchial lymph node, presenting the picture of the sarcomatous form of Hodgkin's disease. Note the large cells, fibrosis, and absence of germ centers.

fibrous bands were wide and made up of many collagen fibrils which separated the gland into irregular alveolar spaces, filled with cells. The greatest number of cells were lymphocytes with large, deeply staining nuclei. Among them were many large cells with clear protoplasm, large cart wheel-like nuclei and one or more large nucleoli. Mitotic figures in these cells were numerous. Some were mononuclear and some had two or more nuclei. There was also a fair number of multinucleated giant cells of the foreign body type which presented typical, dark, evenly stained nuclei. In the peribronchial nodes, the giant cells often contained carbon pigment, while large cells which resembled the "Dorothy Reed" cells did not. Spore-like *monilia* bodies were found.

The pancreas, aorta, adrenals, and other organs showed no lesions attributable to *monilia*.

EXPERIMENTAL LESIONS

Animal inoculations were made to prove the pathogenicity of the *monilia*.

The intravenous injection of rabbits with pure cultures produced death within twenty-four hours. No microscopic studies of this group were made. Rabbits and guinea pigs were inoculated subcutaneously and intraperitoneally. In a week or ten days this group showed abscesses at the site of inoculation and *monilia* were recovered culturally and were demonstrated in the sections with pyronin and light green stains. In animals allowed to live for longer periods the abscesses healed by becoming surrounded by mononuclear leucocytes of the foam-cell type and by encapsulation. Finally, foreign body granulomas were formed containing giant cells filled with mycelial bodies and ovoid forms. Cultures were placed in the nostrils of anesthetized guinea pigs and a diffuse bronchitis

FIG 7 Higher power photograph of lung to show mononuclear cell type of exudate in nodule. A cell resembling a "Dorothy Reed" cell is present in the right center near the top. The dark staining masses were at first believed to be *monilia* but took the bluish green stain with Unna's pyronin and light green, showing that they were fibrin.

produced. Several of these animals died within two weeks.

SUMMARY AND DISCUSSION OF POINTS FOR AND AGAINST HODGKIN'S DISEASE

A Clinical Findings The clinical course indicated some unusual condition other than Hodgkin's disease or some overshadowing concurrent infection. Against Hodgkin's disease were the following points. The patient was in his seventy-first year which is far beyond the average age of Hodgkin's disease. Cases have been reported up to the age of seventy-six but the usual age is between twenty and forty and cases over fifty are rare. There were no superficial glandular enlargements. The symptoms and signs pointed to cholecystitis, arthritis, both of which were present, and to some chronic progressive granulomatous lesion in the lungs accompanied by chills and fever. The lung symptoms coincided closely with the reports of pulmonary moniliasis in the tropics and particularly resembled that condition as described by Farrah¹ among tea tasters in Ceylon. References to the reports of sixty-nine instances of pulmonary moniliasis in the United States were found in the literature since 1915. The fever in our case was of the septic type and was higher than that usually found in Hodgkin's disease. The blood picture was atypical. A secondary anemia did develop in the later stages though the continued leukocytosis of about 17,000 with a relative polymorphonuclear leukocytosis of 86.5 per cent and an absence of eosinophils favored acute infection. The patient was under observation for arthritis for six months

and was in the hospital for the last ten weeks of his life where he was seen daily by various members of the staff, all experienced in Hodgkin's disease, further, unusually complete laboratory work was done without anyone even so much as considering Hodgkin's disease as a possibility.

B Bacterial Findings The organisms recovered are not known to be associated with Hodgkin's disease. *B. coli* and monilia were isolated from the lungs, peribronchial lymph nodes and blood stream. *B. coli* was considered to be a secondary invader. Monilia were unique as an autopsy finding in our experience. They resembled *M. psilosis* though they were not considered identical. There was a heavy fur upon the tongue which could have been the source of a general terminal distribution, though we do not think this likely. We found gram-positive structures in the lung lesions and in some of the bronchioles away from the nodules which we believed to be monilia. The monilia were pathogenic for rats, guinea pigs and rabbits in which they produced chronic abscesses. Smears and cultures of these abscesses were regularly positive for monilia though they could be demonstrated only with the greatest difficulty in the sections, because their morphology, size, and staining reactions varied widely. We considered the monilia the responsible agents for the inflammatory part of the lung lesions, and for the acute lesions in the spleen, but only an accidental association with Hodgkin's disease.

C. Pathologic Findings The pathologic findings were not characteristic and were confusing. The diagno-

sis of Hodgkin's disease rested on the microscopic changes in the peribronchial nodes and upon the presence of "Dorothy Reed" cells in the lesions of the other organs. In typical Hodgkin's disease the lungs may escape entirely, but in this instance the lesions of the lungs were the outstanding pathological features and included organizing pneumonia, acute and chronic bronchitis, as well as the nodules. Inflammatory changes in the spleen were far more acute than typical Hodgkin's nodules. The question arose as to whether the case was a general moniliasis, Hodgkin's disease, or a combination of the two.

Sections were sent to several laboratories and the opinions of various pathologists were not wholly in agreement. Two reported "Hodgkin's sarcoma." Three reported Hodgkin's disease with unusual inflammatory reactions in the lung not typical of Hodgkin's disease. One said that the lymph node lesions would probably be diagnosed Hodgkin's disease in most laboratories, but that the lung lesions could be accounted for on a purely inflammatory basis. Another made a diagnosis of Hodgkin's disease, though he qualified the statement in that he had

seen the same large cells in avian tuberculosis and believed them to be megakaryocytes. One said that the large cells were present in a case of moniliasis of bone which he had studied.

After the demonstration of the monilia-like bodies in the lungs and spleen by means of the pyronin and licht grun stains, we made the final diagnosis as it appears in the title of this report.

CONCLUSION

A case of early Hodgkin's disease is described which appeared to be secondarily infected with a strain of pathogenic monilia. The reaction in the infected areas, as well as the Hodgkin's nodules contained the typical "Dorothy Reed" cells.

Thus finding suggested that these cells are wandering cells which may respond to inflammatory stimuli outside of the Hodgkin's nodules, just as other wandering cells and blood elements are capable of doing.

Spotted Fever Immunization:

Results and Recommendations*

By NOXON TOOMEY, M D , F A C P , *Palmyra, Mo*

CONSEQUENT upon a widening area of distribution and upon the increasing population within the areas that have become endemically affected, the spotted fever of the Rocky Mountains has become of enhancing importance as a public health problem^{218, 223} Of this fact, cognisance has been taken by state and local health officers, by regional and inter-state conferences, by private practitioners, and by the increasing co-operation of the Federal Government. The cooperation of the latter has taken the form chiefly of conducting epidemiologic and ecologic studies in the field, of carrying out laboratory investigations on the virus, and of the manufacture, in annually increasing quantities, of a preventive vaccine of proven, and we might add, great value^{209, 225}

The vaccine, as originated by R. R. Spencer and R. R. Parker has an important place in any control program, but is particularly necessary for use in localities where tick control measures can not be conducted economically, due either to the character of the terrain, the sparseness of the population, or the very occasional character of the menace from spotted fever. Where, however, it has been found profitable to maintain tick control procedures, there is not yet justification

for diminishing the tick control activities because of the recent introduction of a preventive vaccine²²⁴

This paper will be limited to a study of the production, distribution, and efficacy of the spotted fever vaccine as originated by R. R. Spencer and R. R. Parker, the value of the vaccine as compared with other spotted fever control measures being given only incidental consideration inasmuch as this aspect has lately been elsewhere considered in detail by the author.²³¹

The need for a preventive serum or vaccine was early apparent in the study of possible prophylactic measures against spotted fever, as the disease is of great economic importance in the areas where it is most prevalent; as also in areas where it is of (consistently) great virulence^{36, 47, 97} P. G. Hennemann and J. J. Moore^{70, 84} attacked the problem from the aspect of passive immunity. They showed that passive immunization offered virtually no prospect for effective prevention or therapy. It was H. T. Ricketts^{49, 56, 75} and associates^{61, 69}, and later Noguchi^{142, 143, 144} who conducted the first studies on active immunization against spotted fever. Subsequent studies of related nature were reported by Conner^{147, 148}, by Breinl¹⁶³, by Kuczynski¹⁶⁸, and by Otto¹⁷⁷. It was not, however, until the experiments of R. R. Spencer and R.

*Received for publication, March 5, 1932

R Parker resulted in the production of an attenuated virus, in sufficient concentration, that a practical vaccine became available.^{150,153} This vaccine was first released for distribution in 1925

THE NATURE OF THE VACCINE

The vaccine is the spotted fever virus obtained from infected ticks ("tick virus") rather than from the blood of infected animals ("blood virus"), its virulency is attenuated by chemical means. It is standardized for approximate potency by biologic (guinea pig) assay. Each dose (2 c c) equals the attenuation of approximately 20,000 minimum infectious doses for a guinea pig. Two such doses at five day intervals have constituted the standard course, which requires being repeated annually.

Although most vaccines are prepared by heating the organisms to 56° C it has been found necessary to obtain attenuation by means of a chemical, as the protective quality of spotted fever virus is entirely destroyed at the temperature of 56° C.

Manufacture of the Vaccine

Wild adult ticks, collected in the field, are permitted to feed on infected guinea pigs after the onset of the fever, placing about 75 ticks in a wire gauze capsule fastened to each animal. After two days of feeding the ticks are removed and placed at room temperature over moist sand, where they may be kept for several months. Before being used for making vaccine these ticks are again fed, this time on normal animals, for five or six days. This second feeding produces a tremendous increase in the number of minimal infectious doses of the virus per tick. For routine purposes it is not necessary to determine this dosage by the graded injections of the live tick-virus suspensions, as was formerly done.

The partly engorged ticks (male and female) are now ground in a mechanically

operated porcelain mortar and pestle with fine quartz sand and a small quantity of physiological salt solution which contains 16 per cent phenol and 0.4 per cent formalin. After thorough grinding the whole mass is transferred to a large stock bottle, and an additional amount of the salt solution and preservative is added until the concentration reaches, but does not exceed, four ticks per cubic centimeter. After standing for 48 hours, during which time the preservatives will precipitate most of the protein, an equal volume of physiological salt solution is added. This dilutes the preservatives to 0.8 per cent phenol and 0.2 per cent formalin. At this stage the material is kept for seven days at room temperature. This has been found a sufficient period to kill most extraneous organisms, including sporebearers.

The suspension is then diluted once more by again adding an equal volume of salt solution. This final dilution will contain 0.4 per cent phenol, 0.1 per cent formalin, and the killed virus equivalent of one tick per cubic centimeter. The sand, chitin, and precipitated protein is now removed by centrifugation and the remaining clear amber-colored supernatant fluid is ready for the final containers. Occasionally some precipitate forms afterwards. This can be disregarded for it does no harm when injected and besides has protective value. In fact, the discarded heavy precipitates from potent lots may be combined and resuspended in sterile salt solution, again cleared by centrifugation, and the clear supernatant fluid still found to possess high protective value. A number of such lots have been so made and used in human vaccination.¹⁵⁰

Test for Potency and Sterility. Each lot is tested for potency by inoculating six guinea pigs subcutaneously with one cubic centimeter each. After twelve days the animals are given intraperitoneally a test dose of one cubic centimeter of guinea pig blood virus. In four of the six animals no test show symptoms of spotted fever the vaccine is considered suitable for human use. An arbitrary standard of potency is adopted which admits the operation of several factors. The potency of any lot is based on average only approximately the same.

Sterility tests are made on each lot.

with the hygienic laboratory procedure for biologic products

Keeping Quality The vaccine is fairly stable at ice box and room temperature. Ice box preserved vaccine protected guinea pigs invariably up to 200 days and 6 out of 9 pigs at 576 to 597 days. Vaccine kept at room temperature protected 8 of 9 pigs up to 108 days and one-half of 10 pigs at 215 days, the remainder dying of spotted fever

DISTRIBUTION OF THE VACCINE

The vaccine is produced solely by the U. S. Public Health Service at Hamilton, Montana. It is distributed to physicians without charge and it is expected that only a nominal charge will be made for administering the vaccine. Application for the vaccine should be made to the Officer in Charge, U. S. Public Health Service, Hamilton, Montana.

Each year there has been an increasing demand for the vaccine. The heaviest calls are from Montana, Wyoming, Idaho, and Oregon, the last named state using the most in 1930. There is a moderate demand from South Dakota, Nebraska, Colorado, Nevada, and Washington.

The amounts that have been distributed are as follows

Year	C C	Number of Doses	Number of Courses
1925	372	186	93
1926	3,412	1,706	856
1927	6,284	3,064*	1,532
1928	6,500	3,250	1,625
1929	16,600	7,786	3,893
1930	32,000	16,000	8,000
1931	64,000	32,000	16,000

*Includes 312 doses at 25 cc per dose

METHOD OF ADMINISTRATION

Equally good protection has been effected by the subcutaneous, intravenous, intramuscular, and intraperito-

neal routes, the latter employed in guinea pigs only. Ordinarily the vaccine is administered subcutaneously. Attempts to vaccinate animals by forcing them to swallow the vaccine have produced immunity in only a few instances, and failed in the great majority of cases.

REACTIONS

Less than five per cent of four thousand persons have complained of constitutional symptoms. These have included malaise, slight fever, nausea, and aching joints or muscles. Protein reactions with urticaria and edema have occurred in about one per cent of those vaccinated, the symptoms usually appearing very shortly or within a few hours after the injection, but in one instance were delayed ten days. The symptoms last from a few hours to several days, but in one man the urticarial rash persisted somewhat for nine months, finally disappearing following infection with spotted fever. About one-half of those who have reacted after the first injection do not do so on subsequent injections, whereas a few react more violently. Marked collapse occurred in one person who, the next day, felt normal except for weakness.²⁰¹

Local reactions have mostly been inconsequential and limited usually to local redness, swelling and itching about the site of injection. Swelling sometimes extends below the elbow and occasionally to the hand. Itching, the most common complaint, either disappears or becomes scarcely noticeable in persons who have been vaccinated several times.

DURATION OF IMMUNITY

Data from the Bitter Root Valley test indicate that the duration of pro-

tection in the average individual does not exceed one tick season. The period varies in individuals, however, and for some may be quite short. Vaccination annually is therefore desirable.

While effective immunity does not last longer than one year, there is evidence that a residual immunity persists for a much longer time.

POPULATIONS IMMUNIZED

Immunization has included the vaccination of three accurately controlled experimental groups, and a dispersive, not accurately controlled distribution of the vaccine. The general distribution, not available for accurate comparative statistics, was as follows:

In	No of Individuals to Jan 1, 1930	No of Individuals to Jan 1, 1932 (Approximately)
Montana (excluding Bitter Root Valley test group)	401	2,600
(including test group)	(3,231)	(7,100)
Idaho (excluding test group)	203	1,400
(including test group)	(396)	(1,593)
Wyoming	863	2,900
Oregon	30	3,300
Nevada	5	300
Colorado	3	275
Utah, Dakotas and Nebraska	2	275
Washington and Cali- fornia	0	250
General distribution	1,507	8,300
Total distribution	4,530	16,000

The three test or controlled groups were the following: the U S Public Health Service workers (including state control employees), the Idaho Test Group, and the Bitter Root Valley Test Group. The Idaho Test

Group included 94 persons in 1926 and 99 in 1927 (none thereafter), a second annual vaccination not being offered in 1927 to those vaccinated in 1926. The number of inoculations administered to the Public Health Service (including state control) employees is included in the following statistics concerning the Bitter Root Valley Group.

The following table (table I) shows the number of individuals who, in each year, had received the number of vaccinations and revaccinations as indicated by the integers on the course line.

TABLE I

COURSES RECEIVED	1	2	3	4	5	6	7	TOTAL
1925	34							34
1926	624	30						654
1927	846	339	112					1,296
1928	1,469	430	141	11				2,051
1929	2,067	491	191	71	10			2,830
1930	2,550	555	257	143	64	9		3,578
1931*	2,720	800	550	265	150	10	5	4,500

*Estimate by the author, official records not yet compiled for publication.

RESULTS

From the results of a two year test (1926 and 1927) made in southern Idaho (Snake River Valley) against the mildest type of the disease, and another test against the most virulent type, which has been in progress for seven years in the Bitter Root Valley, the following conclusions are justified—that against the milder types of infection the vaccine usually affords full or nearly full protection, while against the highly virulent type the degree of protection is usually sufficient to cause a marked amelioration of the customary very severe symptoms, and to predispose to the recovery of most cases.

In southern Idaho infection is very prevalent among persons handling

sheep on the range, and the test was therefore confined to that industry. During the two seasons of 1926 and 1927, 193 sheep herders were vaccinated, and 364 non-immunes served as controls. A single case only occurred among the vaccinated men (1 in 193). This man had refused the second injection. Among the 364 control individuals there were 22 cases, or one in every 16.55 men.

The Bitter Root Valley case mortality for the twelve years, 1917 to 1928, was 53 deaths out of 69 cases, a rate of 76.81 per cent. In six of these twelve years the mortality for adults was 100 per cent. During the period of the four years under consideration (1925-1929) there were, including the non-vaccinated control group, a total of 18 cases with 15 deaths, a case mortality rate of 83.3 per cent, among the non-vaccinated persons living in the Bitter Root Valley.

The results of the test against the malignant Bitter Root Valley strain yield the following statistics for the period 1925 to 1931, inclusive.

	Vaccinated Group	Non-vaccinated, Control Group
Number of individuals in group	3,578	about 8,700
Approximate ratio to whole population	30%	70%
Number of cases in group	16	30
Case incidence	1/223*	1/290
Died	2	22
Death rate	12.5%	73.32%
(Parker-Spencer series	9.09%	90.91%

*The slightly greater incidence rate in the vaccinated group was due to the fact that vaccination was first carried out to proportionately greater degree in a "well defined

A composition of the Public Health Service (Group A) cases, seven in number (with one death), the Bitter Root Valley cases, 16 in number (with two deaths) and the experience of Dr. E. L. Jewell with two cases (both recovered) each with the equally fatal Kirby Creek strain of spotted fever, gives a total of only three deaths in twenty-five cases of almost fatal virulency, a mortality rate of 12 per cent against the twelve year average of 85 per cent.

Parker and Spencer, writing of their initial series, have been able to say "Considering only adult cases in the Bitter Root Valley as a whole, the recovery of 10 of 11 vaccinated adults, 7 of Group A and 4 of Group B (90.91 per cent recovery) during the four year test period offers vivid contrast, first with the death of 10 of 11 non-vaccinated adults (90.91 per cent mortality) during the same period, and second, with death of 9 of every 11 non-vaccinated adult cases (84.91 per cent mortality) during the past twelve years."²⁰¹

PROSPECTS

Having passed the experimental stage, the prospects for the adequate employment of the vaccine have to do

dangerous zone on the west side of the valley", where of 1,208 persons, 496 were vaccinated, letting the remainder, 712 in number, serve as controls. Considering only the group of 1208 in the dangerous zone on the west side of the valley, there were during the four years (1926-1929) three cases (1 in 165) among the members of the vaccinated group, none of which was fatal, while there were nine cases (1 in 79) among the non-vaccinated group, seven of which proved fatal, a case mortality rate of 77.7 per cent.

with problems of distribution, and of coordinating the use of the vaccine with other control measures, according to the relative economic positions of the measures available. Maximum distribution requires suitable publicity and organization of distributing channels—matters of routine.

The evaluation of the vaccine's economic position is not definitely established, there appearing to be a tendency to undervalue it (compared with other measures) even by those reasonably conversant with the situation. This we believe is a great mistake.

The limited supply, the high cost of manufacture, the disposition of many persons to refuse to submit to any sort of vaccination, the necessity for annual reinoculations, and the popular appeal of other more visibly tangible control measures, such as tick destruction and rodent destruction, all serve to restrict the use of the vaccine to a greater degree than they should.

While it is evident that other control measures can not be diminished the slightest, in areas of great malignancy or tick concentration, on account of the introduction of the vaccine, the great fallibility of these measures renders imperative the systematic use of the vaccine in all dangerous areas, despite the additional cost. In areas of lesser danger the use of the vaccine is equally imperative, as in most such localities the liberal use of tick destruction and rodent destruction measures are economically infeasible. Particularly requiring the vaccine are transient visitors to dangerous areas, and residents of remote or sparsely settled localities in the infected areas. It is particularly the latter class of persons

that present serious problems in the matter of distribution.

In final analysis it is apparent that the prospects for the use of the vaccine are predominately in the hands of the medical men serving in the localities affected, if they energetically sponsor the use of the vaccine they will be supported by the proper persons for obtaining the necessary publicity, if they are negligent the popular appeal will eventually foster an increasing use of the vaccine, but never perhaps to a sufficient degree unless actively supported by the medical profession. Certainly, however, there is no reason to infer that physicians will be remiss in this matter, as the initial response of the profession has been exceedingly gratifying. Nevertheless, to facilitate distribution, various regional organizations and standards need to be created, these are matters of administration, largely being developed at the present time, and will be dealt with as recommendations.

RECOMMENDATIONS

Current problems have to do with methods of manufacture and standardization, means of distribution, educational programs, and plans of inoculation.

The progressively increasing demand for the vaccine will undoubtedly be met adequately by the U. S. Public Health Service for years to come. It may, however, become necessary to require some reallocations in the manner of defraying the cost of manufacture, as the production of the vaccine is exceptionally costly due to the high labor charge for field work in obtaining the ticks and for the laboratory work.

needed to infect them and rear them. Methods of manufacture are, however, being studied from the aspect of reducing unit cost and of increasing potency. A better method for assaying and standardizing potency is desirable.

Distribution through the medical profession should continue as the main avenue of release. In controlled areas and other highly malignant localities, the vaccination should be under the immediate supervision of the statistician in charge. For reaching men on remote sheep ranges, the state sheep inspectors, veterinarians, and other intelligent persons of the locality should be trained to give the vaccine and to keep the records.

As maximum distribution can not be obtained without persistent publicity of the proper sort, it is recommended that newspaper editors, ministers, school teachers, district supervisors, and educators in the higher grades be officially requested to publish the facts concerning spotted fever vaccination, and to give such information of local interest as will facilitate obtaining the inoculations. For this publicity the school and civic exercises of Washington's birthday should be utilized systematically to the end that the date of February 22 shall become firmly associated in the public mind with the need for obtaining the first of the year's spotted fever inoculations. Similarly in areas of great malignancy the same custom should also become identified with May Day, May 1st, for the single mid-season injection. On the other hand, in areas where one injection of the year is the optimum dosage, this fact should be made known to relieve the public mind and to dis-

courage the needless waste of the vaccine.

Regarding dosage and plan of administration, in view of the need of economy and maximum general efficiency, it is recognized that collectively better results will be obtained by so employing the vaccine as to depart from the present standard dosage (two injections of 2 c c each, at five day intervals) wherever local requirements, particularly the greater or less local virulency of the disease, indicate the advisability of establishing an optimum dosage for the locality concerned. Thus a single mid-season injection (about May 1st) in addition to two pre-season injections, is decidedly to be recommended for persons exposed in areas of great malignancy. On the other hand, in certain localities a single annual injection of 2.5 c c, before the commencement of the tick season, should be considered optimal, according to local conditions. In areas of intermediate virulence the optimum dosage appears to consist of two injections of 2 c c each, or possibly the first of 1.5 c c and the second of 2.5 c c, the interval of five days being permissibly lengthened to seven days where local conditions seem to make the latter interval more feasible.

Regarding organization of the distributing channels it is recommendable that state health boards shall (to assist them and the Federal authorities) appoint non-salaried, resident district supervisors among the regular medical practitioners of their State, with view to surveying local requirements, obtaining and supervising proper publicity, keeping records, rendering reports, and otherwise assisting in the

distribution of the vaccine, with consideration to apportioning it where it is most needed

SUMMARY

Six years' experience with the Spencer-Parker spotted fever vaccine, a chemically attenuated form of the virus, has demonstrated it, by several controlled experiments, to be of great and dependable value in preventing the occurrence of the mild type of spotted fever, and of great value in mitigating the severity of the highly fatal type of the disease, the mortality of the latter being reduced from the twelve year average of eighty-five per cent to approximately ten per cent (nine to twelve per cent)

As the protective action of the vaccine lasts only one season (four to twelve months), annual reinoculations are necessary before the commencement of each tick season. Since the introduction of the vaccine in 1925 to the year 1931, inclusive, between 25,000 and 30,000 persons have been vaccinat-

ed, and many of them revaccinated annually from two to six times

The demonstrated value of the vaccine, and the great need for it in endemic areas, has created an increasing demand for it from the medical profession and the laity, a demand that will continue to be met gratis by the U S Public Health Service Laboratory at Helena, Montana, despite unusual difficulties of manufacture and distribution

While it is recognized that tick destruction and rodent control measures can not be safely diminished on account of the introduction of the vaccine, it is of great importance that the vaccine be used adequately and systematically in all endemic areas, as in most areas it is the only preventive measure available that is both dependable and economically feasible. To effect better distribution and economy, several recommendations are made concerning organization, publicity, and modification of dosage with respect to local requirements, according to the virulency of the local strain.

Gastric Secretion—The Electrolytes before and Their Changes at Various Periods after Histamine Stimulation*†

By LAY MARTIN, B S., M D., F A C P., With the Assistance of
MORTEN MORGANSTERN, M D., and M L. CARROLL, A B., *Baltimore, Md*

INTRODUCTION

THE institution of hypodermic injections of histamine as a gastric stimulant, has enabled investigators to obtain undiluted gastric juice with much more facility than previously, no corrections have to be made for dilution by an alcohol meal.

Gamble and McIver¹ determined the amount of fixed base in a Pavlov pouch from the fundic end of the stomach. They found a fairly constant level of Cl^1 but a varying amount of base. The level was low on a meal diet, and high on a fasting stomach. The gastric Cl^1 value (158 c.c. 0.1 N per 100 c.c.) is near the total fixed base concentration in blood plasma.

In a series of interesting and well-controlled experiments MacLean and Griffiths² showed that the introduction of acetic acid, hydrochloric acid, and sodium acid sulphate into the stomach will prevent the secretion of hydrochloric acid until enough neutral chloride has been secreted to dilute the

gastric contents to 0.2 per cent hydrochloric acid or below. Then hydrochloric acid is secreted. The total chloride soon reaches a level (0.11-0.12 N) and remains so, as if "the combined efforts of emptying and secreting tend to adjust the concentration of Cl^1 to a normal maximum level of 0.11-0.12 N". They believe that "secretion of HCl by the gastric glands is a self-limiting process and after its duty is fulfilled the chlorine is kept level by the secretion through the gastric glands of neutral chlorides".

MacLean and Griffiths² were also able to show that dogs having a Pavlov pouch behave in regard to hydrochloric acid and chloride secretion in exactly the same way as normal man: an initial rise in acid then a fall and concomitantly an increase in neutral chlorides, also, that the total chloride in the pouches remains about constant during secretion. They feel that their work definitely rules out the theory of alkalinization of gastric juice by duodenal regurgitation which was advanced by Boldreff³ in 1915.

In a former experiment, these same investigators² determined, by a very delicate method, the amount of CO_2 and dioxide in various specimens of gastric

*From the Gastro-Intestinal and Chemical Divisions of the Department of Medicine of the Johns Hopkins University.

†Delivered in part before the Baltimore Meeting of the American College of Physicians, March 23, 1931.

juice Only when bile was present were they able to demonstrate an increased amount of carbon dioxide Furthermore, the hydrochloric acid curve showed the normal rise and fall whether carbon dioxide was present or absent

On single test specimens of gastric juice, the total bases, the total chlorides, the free hydrochloric acid, and the phosphates were determined by Bulger, Stroud and Heideman⁶ The fasting juice was compared with the secretion stimulated by drink (400 cc of water containing 1 cc of phenol-sulphonphthalein solution) In this way the dilution was corrected The authors showed that very little change occurred in the total chlorides, but that during secretion the total base fell in proportion to the increase of acid. They believe that the chlorine ions and water leave the blood in about the same concentration as that found in the serum There appears to be a definite change in the phosphate content of the human gastric juice which is inversely proportional to the content of HCl Specimens with a phosphorus content as high as 11.17 mg per cent were found in cases of achlorhydria Gastric juice with a high HCl content averaged about 4.5 mg per cent of phosphorus

Polland, Roberts, and Bloomfield⁷ also studied the chloride, base and nitrogen curves before and after histamine stimulation They found that the increase in titratable acidity is due to the greater increase in output of chloride over base, also, that nitrogen is present, and that it varies in proportion to the base

In six cases of anacidity following

histamine stimulation, Bloomfield, Roberts and Polland⁸ found chlorides, bases, and nitrogen in the normal concentration. As the volume of secretion was quite low, the total amount of the substances was naturally much below the average normal

It seemed of interest to know whether more information could be added to these investigations, and furthermore to ascertain what changes, if any, took place in the blood and urine during the phases of gastric secretion This part of the investigation will be presented separately

METHOD

The one hundred and sixteen individuals investigated were in the great majority from the Gastro-intestinal Dispensary of the Johns Hopkins Hospital They presented a multiplicity of complaints and sicknesses and they represented a cross-section of the usual number of admissions. A few estimations were made on patients in the medical and surgical wards, these were selected cases Complete analyses were made on ninety of these 116 patients and the results are recorded below

The individuals to be investigated reported to the clinic after fasting for 15 hours A duodenal tube was passed and its position was seen, by fluoroscopy, to be just beyond the dependant portion of the stomach All patients were cautioned not to swallow saliva. After the removal of the entire fasting contents, each patient was given histamine (ergamine acid phosphate) hypodermically, 0.005 mg per pound of body weight Constant drainage was instituted and the total gastric

secretion was collected and separated into three one-half hour periods

The hydrogen ion concentration was determined by the colorimetric method, using Clark's standards and indicators.⁹ Titratable acidity was determined by the standard method using dimethyl-amino-azobenzene and phenolphthalein as indicators, a definite canary yellow color was taken as the endpoint of the former indicator and the first permanent pink as that of the latter. Total chlorides were determined by the method of Van Slyke,¹⁰ total bases by the method of Stadie and Ross,¹¹ inorganic orthophosphates by the method of Benedict and Theis,¹² CO₂ content by the method of Van Slyke and Cullen¹³ and trypsin by the author's method¹⁴

OBSERVATIONS

For clearness of description the material has been divided as follows

- (a) Those individuals who secrete hydrochloric acid after histamine stimulation

Group I includes cases which contain free hydrochloric acid in the fasting or resting gastric juice. See table I.*

Group II includes cases which contain no free hydrochloric acid in the fasting juice. See table II

- (b) Those individuals who secrete no hydrochloric acid before or after histamine stimulation

Group III includes cases which have a gastric juice with a pH between 3.0 and 8.0, the achlorhydrias. See table III.

*To facilitate reading, the figures, graphs and tables have been placed at the end of the article

Volume

The amount of resting or fasting juice varies within wide limits. Groups I and II from 0 to 190 cc, the achlorhydrias, Group III, from 0 to 95 cc. After histamine stimulation there was almost always a rapid production of gastric juice in the acid producing cases. The amount collected in comparable periods, however, varied within wide limits, the period in which the greatest amount was to be collected, could not be predicted, but usually the maximum was to be found in the first half-hour with decreasing amounts in the second and third. With the production of a large amount of material the consistency became quite limpid, clear and of high titratable acidity. There were cases, however, in which a high titratable acidity was associated with a small volume of thick, mucoid material.

In the cases of achlorhydria, it was quite unusual to collect large amounts. In fact, it was often difficult to obtain sufficient material for the complete analysis. During the various periods it was rare to obtain more than that found in the fasting juice.

Total Chlorides

Chlorides were found in the gastric juice of all patients investigated. The amounts varied within wide limits and in relation to the type of secretion.

The fasting juice of the 25 cases in Group I, hydrochloric acid in all specimens, contained total chlorides between the limits of 88 and 143 milliequivalents per liter, an average secretion of 110. Following histamine stimulation these cases had an increased content in all but four of the

cases, at times rising to a level of 150 to 158 meq,* with a general average of 127. Usually there was a slight decrease in amount towards the end of secretion. There was, however, much less variation in the chloride content than in the acidity as will be shown later.

The chloride content of the acid free fasting juice of the 21 individuals of Group II was found to be within lower limits, 58 to 113 meq and averaged 91. After histamine stimulation, an increase similar to that in the group above was noted and although at times the highest chloride content was equal to Group I, the general average was lower, 114 meq. Here the small increase in chlorides after stimulation in comparison to the corresponding acid rise was even more noticeable.

The chloride content of the fasting juice of the 44 cases in Group III who were unable to secrete free hydrochloric acid in any specimen, was found between the limits of 37 and 115 meq, with an average of 81. After stimulation, there was at times an increase and at other times a decrease in the chloride content, in an exceptional instance the amount rose from 108 to 138 meq, in many cases there was but little change.

The average amounts of the chlorides of the specimens of the three groups have been charted in figure 1 to show the amounts found before and after stimulation. The difference in the levels of the three curves is quite striking.

The cases of Group III, the achlorhydrias, have been separated into four

main subdivisions determined by clinical diagnosis. The subdivisions selected were organic disease of the stomach including carcinoma of the stomach and one case of questionable syphilis, marked nephritis with retention of non-protein nitrogen products, pernicious anemia, and benign achylia. These are shown in figure 2. A study of the figure reveals the following interesting points:

- 1 In the group of benign achlorhydrias, there is a general trend towards a high percentage of chlorides in the gastric juice. The only exceptions to this are Case no 125, an apparently healthy house officer, Case no 121, dementia praecox, and Case no 124, an old colored woman. In this group it is clearly seen that there was no fixation of secretion concentration of the salts.
- 2 The cases of pernicious anemia are able to secrete salts through a wide range of concentration.
- 3 In the severe nephritics the secretion of chlorides in the gastric juice is at the same high level noted in the benign achlorhydrias. The number of cases is too small to draw any conclusion from the small range of concentration strength from specimen to specimen.
- 4 The most important finding in the cases of organic disease is that the great majority of these cases secreted a gastric juice having a low salt content. It is also interesting to note that half of these patients were able to vary the chloride secretion concentration through as large a range as

*Hereafter meq is used as an abbreviation of milliequivalents per liter.

the majority of the benign achlorhydrias. The latter group, however, secreted at a higher level as noted above.

Acidity

Michaelis¹⁵ has shown that all the free hydrochloric acid of the gastric juice has been neutralized when the juice is titrated with alkalis to pH 2.9. This end-point may be recognized (when dimethyl-amino-azobenzene is used as the indicator) when a salmon pink color is reached. Titrating to a canary yellow color gives results a trifle too high but has been used as an end-point in this work as the difference is very small and the end-point much sharper than that encountered in titrating to salmon pink. Michaelis has further shown that beyond pH 3.0 the hydrogen ion concentration in N/10 HCl drops almost perpendicularly to pH 10. A change in this titration curve is due to the presence of acids other than free hydrochloric.

In the tables there are a few cases with a pH beyond 3.0 in which values from 2 to 10 are given under free hydrochloric acid. This is due to the fact that pH 4.0 (canary yellow color) was taken as the end-point for free hydrochloric acid titration.

The twenty-five cases of Group I secreted a fasting juice in which free hydrochloric acid varied from a small amount up to 94 meq. Following stimulation there was an increase of acid content in twenty cases, a few went up to 120 meq.

In Group II where HCl was secreted only after stimulation with histamine, the acid content occasionally rose to the high level of the first group, the

general average was much lower. The relationship between the total chlorides and acid content of all groups is shown in figure 1.

In Group II there were ten specimens which had an hydrogen ion concentration between 3.4 and 5.0 as may be seen by referring to table II, Cases no 10, 15, 16, 24, 25, 61, 64, 107, 118. The hydrogen ion concentration must be due to the presence of acids other than free HCl but at the present time it is impossible to do more than speculate on their nature.

The hydrogen ion concentration in the preponderant number of the achlorhydria cases was found to be about 7.0, if the pH was considerably greater, it is not to be accepted as quite correct since the escape of CO₂ will cause large errors.

In both of the groups secreting HCl there was a rise in acidity subsequent to the histamine stimulation and generally a decrease in the last, the 90 minute, specimen, and at times in the last two specimens. This observation has been made by numerous investigators and is mentioned here not as reiteration but because the interpretation of the diminution has been greatly discussed. A consideration of this point will be given later.

Bases

The change of secretion of total bases into the gastric juice presents an interesting series of phenomena. In Group I (patients who secreted HCl into all specimens) it was found that that amount of base varied inversely to the titratable acidity. In other words during the period of secretion there was a drop in the milliequiva-

lents of total base per liter, and towards the end there was a rise in all cases except nos 43, 54, 113, 116 and 118 where either the HCl or total chlorides did not fall. The amounts found in the fasting juice varied between 26 and 94 meq, the general average of total base was 67. After stimulation the average dropped to 53 meq and ranged between 30 and 84.

In Group II, those patients who secreted no free hydrochloric acid in the fasting juice but did after stimulation, the same phenomena were observed, only more intensified as there was often a very marked drop after stimulation. The total bases in the fasting juice varied between 60 and 120 meq, a general average of 97. After stimulation there was a marked drop to limits between 44 and 90 meq with an average of 66 meq.

In the achlorhydrias, Group III, there was much less change in total fixed base after histamine stimulation, the curve of secretion being almost a duplicate of that of the chlorides of the same group. Figure 3 gives a clear-cut illustration of the changes in the three groups and may be superimposed on figure 1. The total variation in total fixed base in all four periods for the 44 cases was from 34 to 132 meq. The general average for each period was as follows: Control 88 meq; 30 minutes, 88 meq; 60 minutes, 89 meq; 90 minutes, 95 meq.

It is important to note that some cases contained about the same number of milliequivalents of base throughout the periods of collection; i.e., if the fasting juice contained only 50 meq the specimens collected after histamine also contained about the

same number in contrast to the marked changes noted in Groups I and II. Likewise, if the fasting juice contained 100 meq or more the following specimens contained 100 meq more or less. There was an equal number of cases, however, who showed the ability to change secretion strength of bases. As was noted above, the same change occurred in the secretion strength of chlorides.

A very fair estimate of the changes in bases, which have been observed in the subdivisions of achlorhydrias, may be obtained by a reexamination of figure 2, since the figures for base agree more or less with those for the chlorides, although in individual instances it was seen that the total bases were several milliequivalents per liter higher than the corresponding amounts of chlorides per specimen. This very important inequality will be discussed further on.

Ortho-phosphates (Inorganic)

The estimation of inorganic phosphorus would seem to be of some importance since it is usually found in greater concentration than in the blood, except during periods of large volume output and relatively high acidity.

In Group I the limits of inorganic phosphate lie between 0.5 and 3.2 meq of phosphate ion in the resting juice. After histamine there was generally a decrease in the concentration and in cases with high volume output the level decreased, at times, to 0.3 meq.

In Group II the limits of the phosphate in the acid free resting juice lie between 1.1 and 5.4 meq, a substantially higher level than that noted for the resting juice of the preceding

group After stimulation there is usually a decrease in amount but as the volume and acidity of this group seldom reach the heights of Group I, it is rare to find a decrease equal to the limits of Group I

In Group III (achlorhydrias) the limits of the phosphate in the fasting specimen lie between 1.1 and 5.6 As with the chlorides and bases there is much less variation in the amount of phosphate of this group than in Groups I and II The level remained more or less constant throughout the period of observation This is illustrated in chart 1

Carbon Dioxide

In cases where the CO_2 content was estimated the gastric juice was collected under a thick covering of oil It is recognized that the method allows of only an approximate determination but even so it has been possible to account for several apparent inaccuracies in the acid-base ratio The CO_2 content as determined represents minimum values

A recheck of the amounts of CO_2 recovered in relation to the pH of the juice, permits the opinion that, within fairly rough limits, the results are of value The high CO_2 values were always found with cases having a pH beyond 7.0, and at times 8.0 This last figure can be obtained only by loss of CO_2 to the air, as has been said above

In cases in which hydrochloric acid was present in all specimens, Group I, the CO_2 content was usually between 1 and 4 volumes per cent

In the non-acid fasting specimens of Group II, there are unfortunately only five estimations Those specimens analyzed, however, have a CO_2

content of from 10.0 to 14.5 volumes per cent Some of these contained bile After stimulation the CO_2 assumed the same value as in Group I

The estimations made on Group III, the achlorhydrias, showed a general upward trend of CO_2 content, varying from 5.5 to 67.0 volumes per cent In a rough way the CO_2 content was proportional to the pH and had no direct relationship to bile or trypsin content

Trypsin

The measurement of trypsin represents the milligrams of non-protein nitrogen produced from 20 cc of 0.5 per cent casein in phosphate buffer of pH 7.5 by the action of 1 cc of a 1:10 dilution of gastric juice incubated for half an hour at 37.5°C

In Group I amounts varying from none to 4.0 mg have been found The few cases showing a bilary regurgitation have usually been found to have higher values but at times trypsin has been demonstrated in the absence of bile There may be a bile tinge to the gastric juice without any demonstrable trypsin

In Group II there was a marked increase in the amount of trypsin found in the acid free resting juice either with or without the presence of bile The largest amount found was 11.0 mg After histamine stimulation occasionally larger amounts were found than in the comparable specimens of Group I and occasionally trypsin disappeared with the secretion of gastric juice

The achlorhydrias as a group have much the greater content of trypsin, in fact amounts up to 18.0 mg. were not uncommon It was not entirely absent in any specimen but Case number

70 had very small amounts. and strangely enough this patient regurgitated bile

DISCUSSION

It is possible to correlate some of the data at hand and to give some interpretations

In the acid secreting cases a high volume of secretion was always associated with a high content of chloride and hydrochloric acid

As noted under volume the typical case runs its highest secretion during the early periods after stimulation and gradually decreases as the stimulation ceases. From figure 1 it has been possible to show that the same type of curve is also found in the chloride and the acid content of the successive periods. However, the volume, the total chloride and the acid content vary considerably from case to case, and some cases with small volume secretion will have a high chloride and acid content—this occurred in one case secreting a high mucus-like fluid

In chart 2 the relation of volume to total chlorides has been plotted. The achlorhydrias, it is here shown, secrete the chlorides at a lower level and associated with this there is generally a low volume

In chart 3 the relation of volume to acid content has been plotted. In order to be able to include the achlorhydrias, the free hydrochloric plus the so-called combined or total acidity was used. The value of the latter averaged about 10 meq. The same points as in chart 2 are illustrated, i.e., when there is a large volume of secretion, the acid content is high, but here there are some very noticeable exceptions in which a high acid

content is associated with a very low volume

In the specimens without free hydrochloric acid the volume is seen to fall generally below 40 c.c. and, in the large percentage, below 20 c.c. per thirty minute period. The estimation of the combined or total acids, i.e., those substances, acid or buffer, which hold the gastric juice below pH 3.0, has a certain value but it would be erroneous to consider the value as having the same relation to volume as has the estimation of hydrochloric acid.

Influence of Duodenal Regurgitation

It may be interesting to consider the data in regard to the influence of duodenal regurgitation on the regulation of the acidity. Figures 1 and 3, which have been presented to show the relationship between the various electrolytes, demonstrate the fact that in the acid secreting cases there is a normal rise and fall in the acid curve and that furthermore there is a smaller but yet, none the less, definite rise and fall in the secretion of chlorides. In accord with the theory of duodenal regurgitation, the fall in acid should be accomplished by regurgitated alkaline duodenal contents

In order to throw further light on the subject, specimens were examined for the presence of bile and of trypsin. These were noted to appear in a most irregular manner throughout the different periods of extraction. At times one or both of them were found when there was a diminution of acidity in the fourth specimen but as frequently they were not present. They were found not only when there was no decrease in the amount of acid but also when there was no increase in the

amount of the chlorides, making it even more unlikely that regurgitation would explain the changes of acidity.

It is certainly possible for the duodenal contents to diminish the amount of gastric acidity during the periods of collection or duration of normal digestion. This action is of secondary importance, however, as it has been shown that the fall in acidity takes place without its aid and that the amount and strength of hydrochloric acid decreased with the cessation of stimulation.

Amount of Electrolytes Secreted

Figure 4, for ease in comparison, presents the typical secretion of electrolytes of each of the three groups, and of a normal blood serum. The latter represents the findings in one of the cases in Group I, on whom serial blood and urine analyses were made at the time when the fasting specimen of gastric juice was taken. The value for protein is represented by the amount of base fixed by serum albumen and serum globulin at pH 7.35. The albumen-globulin ratio was taken as 1.8. Calculations were made by the formula of Van Slyke et al.¹⁶

$B \text{ protein} = 0.243 \text{ protein}$

The difference between the amount of base and the cation was considered to be due to organic acids.

Rôle of Bases and Bicarbonates

The secretion of base into the gastric juice is interesting. In those cases which have the ability to secrete hydrochloric acid there is a post-stimulation drop in the content of the base which is in inverse proportion to the increase in the content of acid. In these cases it has been shown that ex-

cept for an occasional slight difference (usually within the limit of experimental error) there is a mathematical equality between the determined cations (hydrogen and bases) and the anions (chloride and phosphate). In this relation the phosphate is usually so low that its presence may be disregarded. This agreement is shown clearly in figure 4, which illustrates the relation between base and hydrochloric or free acid with the changes in the chlorides.

The course of a typical case is demonstrated in figure 5. The fasting contents contained 10 meq of hydrogen ion (free HCl) and 75 meq of bases, this was almost exactly counterbalanced by the 83 meq of chloride. During the various phases of secretion this relationship between the anion and cation remained about the same although there was a decided increase in the milliequivalents secreted under the stimulation of histamine.

The relationship between the bases and chlorides in the group of achlorhydrias is shown in graph 5. It is demonstrated that although many of the amounts in the individual specimens are in close accord, there are others, rather numerous, which fall outside the limit of experimental error. This difference is found not only in cases of true achlorhydria but also in the acid-free resting juice of patients who secreted hydrochloric acid after histamine stimulation. See Cases no. 88, 95, 102, 112, etc.

In Case no. 95 which secreted acid after histamine stimulation the relationship between the anions and the cations of the acid-containing specimens was almost equal as is seen in figure 6. In the fasting juice of pH

70 the bases were greater than the chlorides by 15 meq. The carbon dioxide content of the specimen was 11 meq, and of the acid-containing specimens about 3 volumes per cent, too small an amount to be of significance.

A consideration of the achlorhydrias shows that the content of CO_2 plays an important rôle in equalizing the base and acid columns. Case no. 112 has been selected from a series of similar cases to illustrate this point in figure 7. There are, however, cases of achlorhydria from which but small amounts of CO_2 have been recovered. These are generally cases whose gastric juice has a pH below 7.0.

It is known that the CO_2 content of hepatic duct bile and pancreatic fluid is high and consequently it seems only reasonable that the regurgitation of these fluids into a nearly neutral gastric juice would result in the presence of CO_2 . In this series several of the specimens on which CO_2 determinations were made showed no evidence of bile and also the trypsin estimations were not unusually high. Consequently it seems quite definite that CO_2 is present in the achlorhydric gastric juice of human beings.

The Comparison of Total Chlorides of Gastric Juice and Blood Plasma

The amount of chlorides of the gastric juice in one case reached 158 meq, a considerably higher figure than that of the blood serum, although the sum of the blood serum bases is about equal to it. In the majority of cases the amount was much lower, making a general average for 46 cases of 120 meq of gastric juice chlorides. Therefore, although the milliequivalents per

liter of chlorides secreted were lower than the total number of anion or cation milliequivalents per liter of the blood, the chlorides of the gastric juice of the cases of Group I are almost always higher than those of the blood serum.

The acid free resting juice of patients who have the ability to secrete hydrochloric acid after histamine had an average of 91 meq of chloride, varying between the limits of 58 and 113. This may be compared with fasting and secretion juice of the true achlorhydrias in which there was a general average of 83 meq, varying between 37 and 115. In both of these groups the chloride level was always lower than the total milliequivalents per liter level of bases in the serum but sometimes was above and sometimes below the level of the serum chlorides.

The Secretion Concentration of Bases and Free Hydrochloric Acid

The point cited above naturally led to the question of the secretion concentration of the salts and acid found in the extracted gastric contents. The term *secretion concentration* is used to represent the concentration at which the salts and free hydrochloric acid are produced by the cells before dilution. The easier method of approach would seem to be by determination of the secretion concentration of salts in cases of achlorhydria and in the acid free resting juice of Group II.

- a To see if there was a marked difference in secretion concentration from case to case
- b To determine the changes, if any, which took place at various periods of analysis in the cases of achlorhydria

As a solution to the first problem

several cases have been collected into table V. The sixth column shows that in the acid free resting juice and in corresponding achlorhydria specimens there is a marked variation in the base content from case to case. When the total content, as determined, was reckoned as the equivalent quantity of sodium chloride (NaCl), the salt content so calculated approximated the actual salt content of the juice but did not include the Na_2HPO_4 and NaH_2PO_4 . Since there are no complicating factors such as a change in the chemical constituents of fluid, the concentration of salts in the extracted material represents their secretion concentration into the gastric juice. Furthermore, it must be kept in mind that this fluid is a different fluid from that which appears with the acid secretion in which there is a change in the chemical constituents. Consequently within the limits set in the above argument there is considerable variation in the secretion concentration of salts into the unstimulated acid-free, and the achlorhydria, stomachs.

The secretion concentrations in the former group varied from 333 to 650 mg per cent. In the stimulated and unstimulated gastric juice of the achlorhydrias, the variation was even more pronounced, namely from 225 to 794 mg per cent.

The solution of the second problem, as far as the cases of achlorhydria are concerned, is equally simple and the results may likewise be seen in table V. There was always some, and frequently much change. In one of the cases of pernicious anemia, an initial fasting secretion concentration of 232 mg per cent was increased to 637 mg per cent after histamine stimula-

tion. Case no 44 is of some interest because hydrochloric acid appeared only in the 60 minute specimen. The salt concentration in the fasting juice was 510 mg per cent, changing to 435 mg per cent in the specimen collected for 30 minutes after stimulation.

Another group of these cases, however, showed but little variation in secretion concentration from specimen to specimen. It has been impossible to make any satisfactory classification for diagnosis on the basis of stationary or changing levels of secretion concentration after stimulation.

The determination of the secretion concentration of the salts in the acid secreting cases is not simple because the question of the influence of other molecules such as HCl in varying quantities is to be considered. This in turn brings up several points about the secretion of the hydrochloric acid which would be interesting to solve.

- a Is it secreted at different concentrations in different individuals?
- b Is it secreted at different concentrations at various phases of secretion in the same individual?
- c When the secretion of hydrochloric acid takes place does the stomach secrete salts at the pre-stimulation level or does it secrete them at higher or lower levels?

Before these questions can be answered, a few ideas must be explained.

With the production of acid there is always an increase in the content of chlorides but this increase is insufficient in amount to account for all the hydrochloric acid. This inequality is compensated for by a drop in the amount of base, as has been seen in figures 1 and 3. This decrease in

have nothing to do with the secretion of base and be only a result of dilution by hydrochloric acid in the presence of an increasing or decreasing salt secretion, either in respect to amount or to concentration

As an essential point in this theory of secretion it is necessary to admit of two types of cells: one group secreting hydrochloric acid in pure solution; the other secreting the various bases as salts (chiefly as chlorides). The anatomical arrangements of the organ and its physiology makes it rather difficult to promulgate another belief. This is especially true in consideration of the secretion concentration of salts in the cases of achlorhydria.

The method for the determination of the secretion concentration is as follows. In Case no 98, there were 45 cc of gastric juice extracted as fasting secretion. This contained of base, 85 milliequivalents per liter; acid, 10 milliequivalents per liter; phosphate, 0.8 milliequivalent per liter; and total chloride, 75 milliequivalents per liter. Due to its small amount, phosphate may be left out of the reckoning. Base has been calculated as NaCl with a molecular weight of 58, and therefore a milliequivalent or 1 cc. contains 0.058 gms NaCl. The molecular weight of HCl has been calculated as 36 and a milliequivalent as containing 0.036 grams HCl.

The amount of free HCl in 45 cc
10 milliequivalents per liter
 01×45

But $10 \text{ meq HCl} + 75 \text{ meq NaCl} = 85 \text{ meq}$
And HCl represents

Therefore

And X, the grams HCl in 100 cc
But

And therefore HCl as secreted by the acid producing cells before dilution

But since
and
and

Therefore X, the grams of HCl in 100 cc or the secretion concentration of HCl as secreted by the acid producing cells before dilution, is by interpolation as follows

$$\begin{aligned} X &= \frac{100 \times 0.162}{45 \times 0.1176} = \frac{100}{45} \times \frac{0.162}{0.1176} \\ &= \frac{100}{45} \times \frac{45 \times 0.036 \times 0.1}{10/85} \\ &= \frac{100}{45} \times \frac{45 \times 0.036 \times 0.1 \times 85}{10} \\ &= 10 \times 0.036 \times 85 \\ &= 0.10 \times 0.036 \times \text{number of} \\ &\quad \text{milliequivalents of total} \\ &\quad \text{chlorides in the specimen} \end{aligned}$$

The same formula may be used in estimating the secretion concentration of sodium chloride by substituting 0.58 for 0.036

It has already been shown that in the cases of achlorhydria and in the acid free resting juice of patients who secrete free hydrochloric after histamine the secretion concentration of sodium chlorides (bases calculated as NaCl) is subject to wide variation, not only from patient to patient, but in successive samples taken before and after histamine stimulation in the same patient. By the use of the formula just explained, it has been possible to bring to light several interesting observations on acid containing specimens

- (1) Hydrochloric acid was secreted at varying concentrations between the limits of 316 to 564 mg per cent. This applied to all the specimens from the 46 acid secreting patients of Group I and Group II.

During the period of observation on the average patient (before and after histamine stimulation) there was a change in the secretion concentration of hydrochloric acid. It was lowest in the fasting specimen and rose to its highest level during the height of stimulation, usually to fall somewhat towards the end of stimulation. With the diminution of secretion concentration there was also a decrease in volume of free hydrochloric acid. In other words the concentration of the pure hydrochloric acid solution as secreted followed a curve similar to that of the secretion of the determined total chlorides as in figure 1.

- (2) Sodium chloride was secreted at varying concentrations between the limits of 510 and 916 mg per cent. This also applied to all the specimens of Groups I and II.

That which was true of the variation of secretion concentration of free hydrochloric acid in individual cases, is true also of sodium chloride. The lowest secretion concentration was generally found in the resting specimen and the highest during the height of stimulation to fall off slightly towards the end of secretion. In one important manner there was a lack of parallelism to the free hydrochloric acid secretion concentration towards the end of stimulation there was a fall in the volume of hydrochloric acid secreted. This was not so markedly reflected in the salts since usually the post-stimulation volume of secretion of salt solution remained at the same content for some time. The secretion concentration of base calculated as NaCl varied directly as the secretion of the determined chlorides. This is as true of the achlorhydrias as of the acid secreting cases.

The increase in the percentage concentration of hydrochloric acid in the extracted material is, therefore, due to two factors (a) the increased volume output of hydrochloric acid produced by the stimulation of the acid secreting cells and (b) to the increased concen-

centration of the acid produced by the cells at the height of stimulation

The diminution found in the concentration of salts in the successively extracted acid containing specimens is also due to two factors (a) Although the volume of salt solution secreted may be somewhat increased, the volume secreted is relatively small in comparison to the volume of acid solution secreted. The figures for this statement are included in table V (b) If the salt secretion strength had continued at the prestimulation level the concentration in the extracted materials would have been still lower as is seen in table V, therefore, its ultimate content could only have been produced by increase in secretion strength

CONCLUSIONS

Neutral salts, phosphates, and CO_2 are normally secreted into the resting stomach. There is no constant strength at which the CO_2 and the salts are secreted as they vary markedly in different patients. Hydrochloric acid may or may not be found in the resting juice, its presence probably represents a different physiologic process than that represented by the resting state.

Histamine provokes an increased secretion of gastric juice into most stomachs. It is probably normally accompanied by the secretion of hydrochloric acid. A large volume of secretion was always accompanied by free acid. It seems that acid is secreted throughout the duration of the stimulation and that as the stimulus wears off the production of acid ceases, and

the secretion returns to its resting state. The volume of secretion tends to run a course parallel to the acid. Variations, which may be pathologic, have been noted from this statement and qualifications have been listed above. As the amount of acid increases there is an increase in the secretion concentration, this is also true within the restrictions noted above.

The secretion of the neutral salts continues during the period of stimulation and increases in secretion concentration parallel with the acid. On the other hand the volume output is considerably less than that of hydrochloric acid and a diminishing percentage content of the neutral salts is found in the extracted material in contrast to the increasing percentage of hydrochloric acid. As the stimulus to secretion wears off the production of hydrochloric acid ceases. The volume of salt solution secreted by the cells also diminishes but evidently the concentration of the salt solution continues at a more elevated level for a varying period of time.

Phosphates diminish in concentration in the extracted juice during the successive half-hour periods of observation.

CO_2 is not found in the juice containing free hydrochloric acid but appears in amounts related to the pH of the achlorhydria juice.

The gastric mucosa of many achlorhydrias still retains the ability to secrete salts at various concentrations although for some unknown reason the ability to secrete hydrochloric acid is lost.

FIG 1 Composite chart of total chlorides and free hydrochloric acid in Groups I II and III Variations before and after histamine stimulation as averaged from 20 or more cases per group

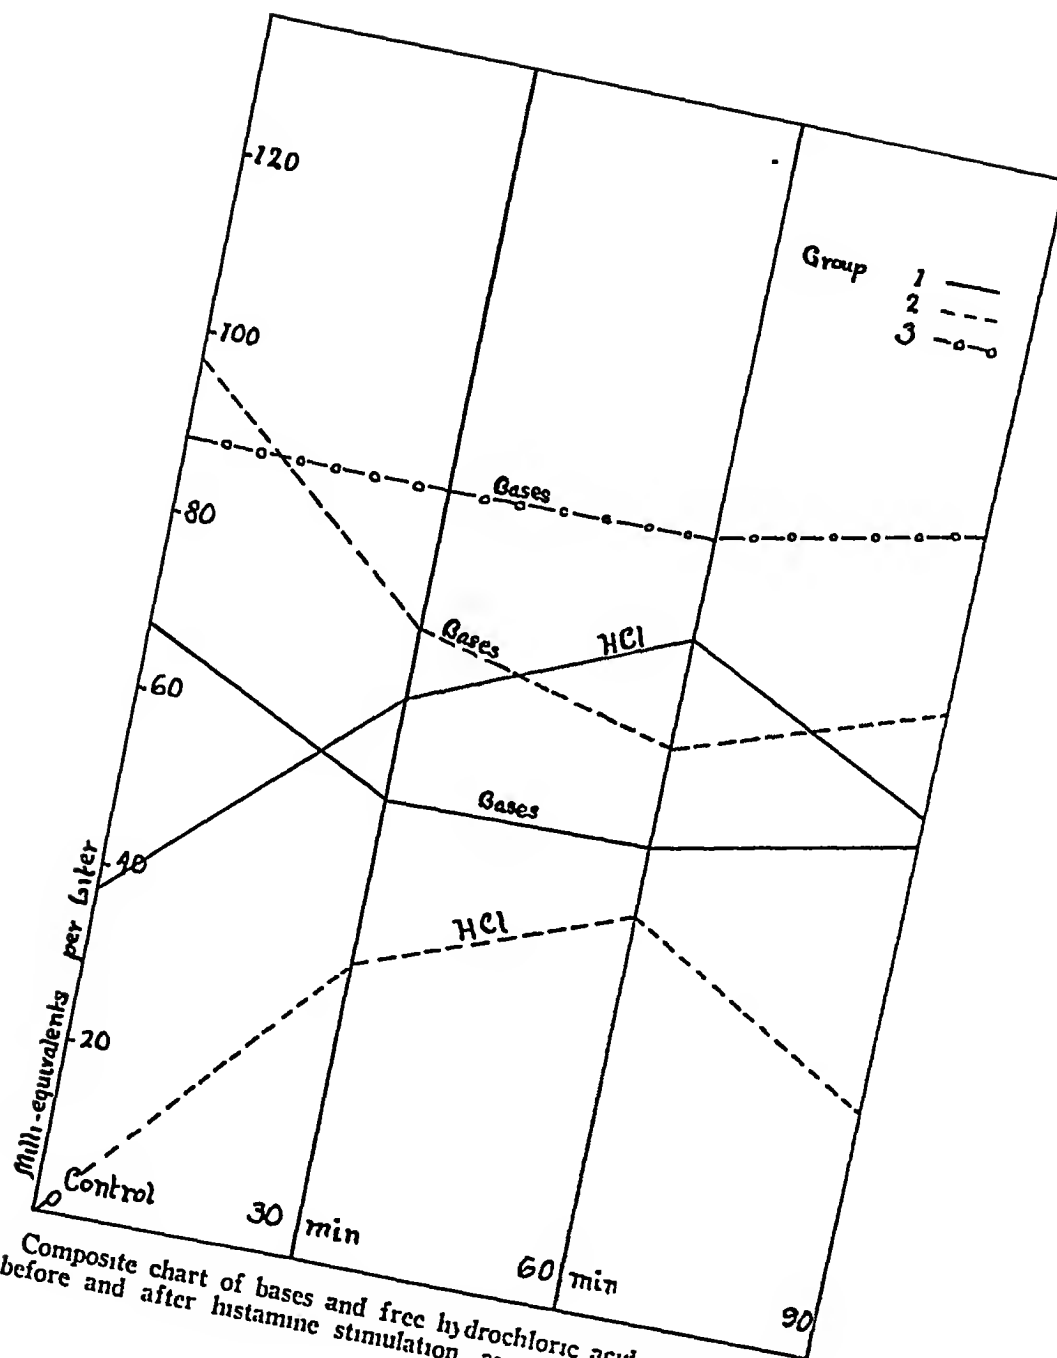

FIG 3 Composite chart of bases and free hydrochloric acid in Groups I II and III Variations before and after histamine stimulation, averaged from 20 or more cases per group

FIG 4 Comparison of the total electrolytic content of typical specimens of gastric juice with the electrolytic content of normal blood serum

FIG 5 Typical normal case of Group I showing electrolytic changes during histamine stimulation

FIG 6 Typical normal case in Group II showing electrolytic changes during histamine stimulation

FIG 7 Typical case in Group III (achlorhydria) showing electrolytic changes during histamine stimulation.

CHART 1 Relation of total acidity to phosphorus in gastric juice

CHART 2 Relation of total chlorides to volume of extracted gastric juice in the several groups

CHART 3 The dots, crosses and squares represent the relation of total acidity to the volume of the extracted specimen of gastric juice in fifty cases. The block figures represent the percentage of specimens for each group arranged according to the volume content. The entire 102 cases were used in the estimation.

CHART 4 Relation of free hydrochloric acid to bases and total chlorides

CHART 5 Relation of total acid to bases and total chlorides in specimens with pH 30 to 80

TABLE IV

Computation of the percentage of HCl and NaCl in extracted specimens
 From this is figured the strength at which these chemicals have originated in pure solution and the amount of that solution in c c The calculation is given on page 18

The First Aphorism of Hippocrates*

By GEORGE DOCK, M D , Sc D , F A C P , *Pasadena, Calif*

WE all claim descent, as physicians, from the philosophers and physicians of the great period of Greek civilization, the fifth century, B C , and yet in the rapid increase of current literature we may easily forget what that means. Of course, we can easily revive our knowledge in any of a number of excellent works on Medical History, old or new, or, we can reread any chapter or number of chapters in the Hippocratic Writings. In the following I have chosen one book, namely, the Aphorisms, and traced it down through the centuries, at long intervals, to be sure, seeing how it was reflected by the mind of the most brilliant Greek physician of Pergamos and Rome in the second century, A D ; by some outstanding Arabs of the ninth, tenth and eleventh centuries, a keen and practical Englishman of the fourteenth century, and then through the busy days of early book-printing down to our own time. Ancient and modern critics agree that a great deal, at least, of the Book of Aphorisms is the work of Hippocrates himself, although admitting that additions and alterations have been made. The earliest commentator we know, Galen, believed Hippocrates

produced the Aphorisms in his old age, and as one of the latest commentators, Francis Adams, has said, no one could have written them but one who had long been familiar with the phenomena of disease, and had maturely reflected on all the various subjects to which the Aphorisms relate. That the work was highly valued in the centuries immediately following the lifetime of the author we can gather from the fact that it was taken up by the School of Alexandria, where it was codified and preserved, and in time reached Galen, who, with characteristic enthusiasm and energy arranged the Book of Aphorisms in seven sections, added his own Commentaries and so enabled it to come down through the Dark Ages and not only survive the downfall of Galenism but be used as a text-book up to the time of the discoveries of Percussion and Auscultation, and of the Cell. The characters of the two men, Hippocrates and Galen, have been vividly analyzed recently by Charles Greene Cumston.*

The next name that comes down to us with that of Hippocrates is Hunan, or Honem ben Ishak, a Nestorian Christian better known as Joannitus, born about 809 A D . in a village in Mesopotamia, and the most learned among the translators from Greek into

*"Histoire de la Medecine" Paris 1931

Arabic Joannitius was the author of one of the most celebrated "Isagoges", or Introductions to Medicine. Used in the Middle Ages as textbooks in manuscript, these were highly regarded and were therefore among the earliest medical books to be reproduced by printing. I have been fortunate enough to examine a very good example in the library of Dr LeRoy Crummer. Spelling, capitals and abbreviations show the influence of manuscript methods. The title is "Ysagoge Johannis / Incipiunt Ysagoge Joannis / adtegni galien". The place of publication was probably Lyons, the date 1510. Like other similar works, this contains the "Libri afforismorum domini Ypocratis", in Latin, translated from the Greek by Theodorus Gaza, "medicus". Some of the Introductions had the title "Articella", or "Artisella", from the fact that they contained the "ars parva" of Galen, also called the "Techni" or "Tegni" in various copies, and not from "Articella" as sometimes thought. "Artisella" was the title of a Venetian imprint of 1491. Dr Crummer has a good example printed in Florence in 1534.

That remarkable character, Suidas, a Greek biographer and lexicographer, who lived in the end of the tenth century, spoke of the Aphorisms as surpassing the human mind. An Arab version bearing the date 1100 A.D. is thought to have been the most ancient manuscript on linen paper, parchment and papyrus having been used before. The statement shows how scholars habitually ignored the Chinese, for they used paper from the second century, B.C. The Arabs came into

possession of some in 751, when a Chinese army attacked Samarkand, and paper-making then spread all through Arabic lands and thence to Europe. It is said that the oldest recorded Western document on paper is a deed of King Roger of Sicily, in 1102.

Constantine, called the African, one of the ornaments of the School of Salerno, where he became a monk, translated the Aphorisms with the Commentaries of Galen into Latin late in the eleventh century, this being the first work of Galen to be put into Latin. Rabbi Moses Maimonides, born in Cordova in 1135, called The Great Maimonides, and better known as philosopher and Talmudist than physician, included in his writings a Commentary on the Aphorisms.

How vital the Aphorisms were in the education of the medieval medical student we can see by a conspicuous example. John of Gaddesden, supposed by some to have been the original of "The Doctour of Phisyk" of the "Canterbury Tales", studied medicine at Oxford about 1303. For "inception in medicine", which apparently included the taking of the B.M. degree at that time, he had to have read one book of Galen or one book of the Aphorisms of Hippocrates. So well did John study the aphorisms that he quoted them one hundred and twenty times in his great work, the "Rosa Anglica", written in 1314. A System of Medicine "from head to feet", this was widely used in manuscript in the fourteenth and fifteenth centuries. There are three copies in the British Museum; one, dated 1356, in the Bibliothèque Nationale in Paris, and one

each in the Bodleian and in Merton College library. It was printed in 1492 (Pavia), 1502 (Venice), 1517 (Pavia), 1595 (Augsburg)*. The "Surgery" of Guy de Chauliac, father of French surgery and most celebrated surgeon of the middle ages, first published in 1363, also shows familiarity with the Aphorisms. In the great medieval medical schools of Salerno and Montpellier, Hippocrates and Galen were the two authors whose works were especially studied. Salerno, indeed, was called *Civitas Hippocratica*.

Two and a half centuries after Gaddesden, we find the youthful Felix Plater, who became one of the best observers and one of the most judicious writers of the sixteenth century, studying for the doctorate in Basel. When he took his final examinations in 1557, he was called upon to explain, among other questions, an aphorism of Hippocrates, (the first in section three) reading "*Mutationes temperum pariunt morbos*"**. Another century later, about 1647, Sir Thomas Browne advised a correspondent "that Hippocrates' Aphorisms should be conned for the frequent use which may be made of them" (Pickering Ed, 1836).

The editions of the Aphorisms before 1500 are not accurately known. After 1500, and including those in "Complete Works" of Hippocrates and of Galen, in *Isagoges* and *Articellae*, the number is so large that some

writers think the Aphorisms have been printed oftener than any other profane work. A-J-L Jourdan and F-G Boisseau, in the *Dict des Sci Méd*, *Biographie Médicale*, *Art Hippocrate*, T 5, Paris, 1822, give forty editions between 1532 and 1800.

J-E Dezeimeris, *Dict Hist de la Médecine, anc et mod* T III, Paris, 1836, gives a still larger number of editions, including many incunables, and also including *Articellae*, and combinations of various works, Hippocratic and others, with the Aphorisms. He mentions fourteen French versions up to 1835, and 27 versified paraphrases, chiefly Latin. The number of Commentaries on the Aphorisms, as Dezeimeris says, is immense, and he names many in his very interesting article. The greatest number of "Aphorisms" I find in a single list is that in the Catalogue of Printed Books of the British Museum, 1889, viz, 134 editions of the Aphorisms as separate works. Many languages are represented including Greek, Arabic, Latin, Italian, Spanish, Hebrew, English and French. Of Greek and Latin texts, there were 13 in the sixteenth century, 19 in the seventeenth, 6 in the eighteenth, 1 in the nineteenth. Greek and English, one in 1831. In Latin only, 5 in the fifteenth century, 29 in the sixteenth, 29 in the seventeenth, 10 in the eighteenth. Latin and French 3 in the seventeenth century. French only 1557, 1660, 1685. Italian only 1621; English 1550, 1585, 1610, 1655, 1693, 1708, 1735. In German, 1825, 1840. An Arabic text of *Humay ben Ishak* was printed in Calcutta in 1832. But this number is incomplete and an effort to correct it from bibliography is

*H P Cholmeley, John of Gaddesden and the *Rosa Anglica*. Oxford, 1912.

**Brief Notes on Felix Plater with Extracts from his *Memoirs* preserved in the Library of Basel. By C G Cumston. Johns Hopkins Hosp Bull April, 1912.

does not seem worth while. The many versified translations suggest that it was probably a popular pastime in the early years of the revival of learning to turn the Greek prose into Latin verse, or rarely a modern language. The places of publication include all the well-known seats of printing. The number of editions depended to a great extent on the free-trade in printing, especially that dealing with copies of the classics, in the original tongues as well as in Latin translations.

In size, we have everything from quarto to 32mo, pocket sizes being numerous from the earliest printing. The editors include all the great restorers and commentators of Greek medicine. One of the most celebrated, although better known at present as a comic writer than a medical guide, was Francois Rabelais, the biographer of Gargantua and Pantagruel. His talents were well known to his contemporaries. Familiar with Greek, Latin and Arabic, made bachelor at Montpellier in 1530, he lectured on Galen and Hippocrates in 1531. Dr A. F. Le Double (Rabelais Anatomiste et Physiologiste, Paris, 1899) has shown the extent and accuracy of his anatomical knowledge. Gargantua began to appear in 1533, but in the preceding year Rabelais had published a Greek edition of the Aphorisms, and in 1543 and 1545 he published Latin versions of the latter from the translation of Nicholas Leonceno. Dr LeRoy Crummer has a very fine example of the very rare Ionic text (1532), bound with the Aphorisms (1545) and three other Hippocratic chapters and the Ars medicinae of Galen. Many of the editions of the sixteenth and seventeenth

centuries included the Commentaries of Galen. A careful study of the latter might explain the disinclination to original work so evident in students of those days. Besides the seven sections of Galen, almost universally followed, there was sometimes an eighth, containing Aphorisms thought to be apocryphal.

The lack of classification is remarkable, and Dezeimeris rearranged the Aphorisms according to a simple clinical classification, which I shall follow in making some selections, using the edition of 1841. The English text of Francis Adams (Sydenham Society, London, 1849), the scholarly surgeon of Banbury, the French of E. Littré (Paris, 1844), and the German of Robert Fuchs (Munich, 1893) are convenient for modern readers.

My early studies of the Aphorisms

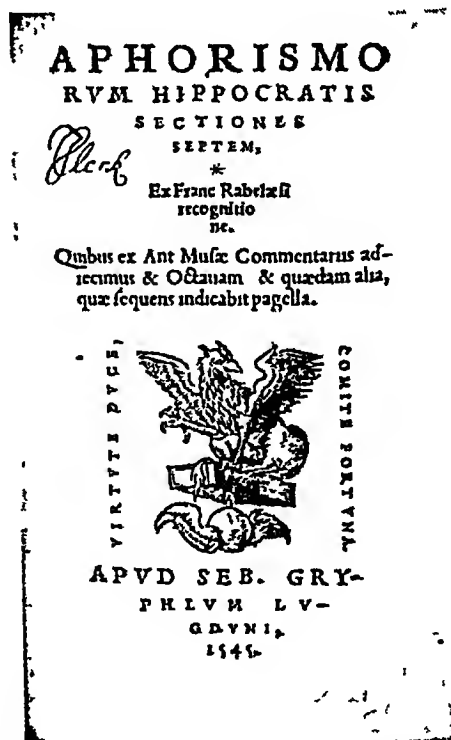

FIG 1 Title page of 1545 Aphorisms, edited by Rabelais, from specimen in the collection of Dr LeRoy Crummer

FIG 2 First page of Ionic Greek text of the Aphorisms, edited 1532 by Rubelius bound with No 1 and other Hippocratic writings

English literature of medicine has proved a complete failure"

Of the numerous definitions of an aphorism, I think one of the best is Adams' version of Galen's, viz, "a writing remarkable for brevity and point". Brevity is a constant feature of the Hippocratic writings, and in the Aphorisms this has been carried so far

that none of the commentators has been able to follow the example. As to the object of the work, I accept the suggestion made by many others, that it was intended to be a comprehensive treatise on the physical science, physiology and medicine known at that time. This explains the inclusion of the aphorisms about seasons,

COMMENT. DE GAL.

Ce que cy apres sera dit dedans ce livre des Aphorismes. I. Breche.

APHOR. I.

Vita brevis, ars verò longa, occasio autem preceps experimentum periculofum, iudicium difficile. Nec solum seipsum præstare oportet opportuna facientem, sed & ægrum, & assidentes, & exteriora.

*La vie est briefue, mais l'art est longue, l'occasion est soudaine & legerement passe, l'experience perilleuse & dangereuse: le iugement difficile. Et ne se faut seulement mon-
strer faire bien son deuoir: mais aussi faut que le patient face de sa part ce qu'il doit, & les ministres & seruiteurs qui sont autour de luy soient tels qu'ils doiuent estre: & que les choses exterieures soient conuenables, & ainsi qu'il appartient.*

Gal. Il est tenu pour certain, presque entre tous les expositeurs, que ceste oraison, soit qu'elle fust en vn, ou plusieurs Aphorismes, est le proème & prefation de tout l'œuvre. Mais ce n'est

and the nature of waters, while the parts on the symptoms, prognosis and treatment are appropriate. There are about four hundred separate aphorisms, some of them expressing truths that twenty-three centuries confirm, and others reflecting errors handed down from the infancy of anatomy and physiology. The wealth of material goes far to explain the great regard in which the work was held in the Hippocratic dawn of medicine, as well as in the urge of the Renaissance, while the far greater bulk and the ever-growing complexity of post-Harveyan medicine removed the primitive advantage, and in time made the Aphorisms unnecessary, if not practically useless. I think, however, that the undergraduate in his first vision of clinical medicine, still more, the interne, might gain much pleasure, and perhaps get an intellectual stimulus from an occasional perusal of this ear-

FIG 6 The First Aphorism from No 5 Compare the Greek text with that of No 2

ly work, and perhaps be led to a more serious study of other chapters of ancient medicine

The First Aphorism serves as an Introduction, or Prolegomenon, in the edition of Dezermeris, and as I wish to give it special attention I pass on to another often alluded to (Section II. Aph 22). "Diseases which arise from repletion are cured by depletion, and those that arise from depletion are cured by repletion, and in general diseases are cured by their contraries." This is sometimes mentioned as the original "contraria contrariis curantur."

ur", but the idea is better expressed in another Hippocratic work "On the Places in Man" It does not seem to require any discussion now Under the sub-title, "The Art of imitating the curative processes of Nature", we find, I 21 "Those things which require to be evacuated should be evacuated, wherever they most tend, by the proper outlets". Cosmetics and general prognosis join in II 54 "Largeness of person in youth is noble and not unbecoming, but in old age it is inconvenient and worse than a smaller stature" Signs of imminence of disease may be represented by II 5 "Spontaneous lassitude indicates disease" Uroscopy has eight aphorisms relating to it, VII 34 being one of the most interesting "When bubbles settle on the surface of the urine, they indicate disease of the kidneys" If this means bubbles that remain after shaking the urine, from albumin in the latter, we can only wonder how such knowledge can be explained without experience with autopsies It seems to represent a different kind of observation from that in II. 33 "In every disease it is a good sign when the patient's intellect is sound, and he is disposed to take whatever food is offered to him, but the contrary is bad" Equally sage is II 19 "In acute disease it is not quite safe to prognosticate either death or recovery" And II 42 "It is impossible to remove a strong attack of apoplexy, and not easy to remove a weak one". In V 10, we may not agree with the time element, but the general thought is suggestive "Persons who escape an attack of quinsy, when the disease is turned upon the lower lip, die in seven days; or if they pass these they become affected with

empyema" That Hippocrates was far in advance of his time in his knowledge of pleural disease is generally known A good example is shown in VII 44 "When empyema is treated either by the cautery or incision, if pure and white pus flows from the wound, the patients recover; and if mixed with blood, slimy and fetid, they die" VI. 27 "Those cases of empyema which are treated by incision or the cautery, if the water or pus flows rapidly all at once, certainly prove fatal" An interesting statistical observation is given in V 9 "Phthisis most commonly occurs between the ages of eighteen and thirty-five" V 12 is not so clear "Phthisical persons, the hair of whose head fall off, die if diarrhoea set in"

FIG 7. From J-E Dezeimeris' *Résumé de la Médecine Hippocratique, ou Aphorismes d'Hippocrate classés dans un ordre systématique*, etc Paris, 1841

The doctrine of critical days is a serious difficulty in Hippocratic writings. A good example, in the sense that it is hard to understand, is IV 64 "When in cases of fever jaundice occurs on the seventh, the ninth, the eleventh, or the fourteenth day, it is a good symptom, provided the hypochondriac region be not hard. Otherwise it is not a good symptom." The very important doctrine of crises has a good example in II 12 "What remains in disease after the crisis is apt to produce relapses", but II 23 seems more dogmatic than useful "Acute diseases come to a crisis in fourteen days", unless we accept the explanation that we have here a definition of an acute disease. II 2 illustrates prognosis in a simple form "When sleep puts an end to delirium, it is a good sign", also, II 16 "When in a state of hunger, one ought not to undertake labor", and II 48 "In every movement of the body whenever one begins to feel fatigue, it will be relieved by rest", and II 4 "Neither repletion, nor fasting, nor anything else, is good when more than natural." II 21 has an appeal in these days of depression and secret ballots on Prohibition, "Drinking strong wines cures hunger", and II 11 belongs to it "It is easier to fill up with drink than with food." A good example of thoughtful medical observation is reflected in I 14 "Growing bodies have the most innate heat, they therefore require the most food, for otherwise their bodies are wasted. In old persons the heat is feeble, and therefore they require little fuel, as it were, to the flame, for it would be extinguished by much. On this account, also, fevers in old per-

sons are not equally acute, because their bodies are cold." There are many aphorisms on diet. I 4 reads "A slender and restricted diet is always dangerous in chronic diseases, and also in acute diseases, where it is not requisite." And again, "A diet brought to the extreme point of attenuation is dangerous, and repletion, when in the extreme, is also dangerous." II 38 shows a diplomatic method still useful in practical dietetics "An article of food or drink which is slightly worse, but more palatable, is to be preferred to such as are better but less palatable."

Therapeutic directions are numerous and varied. II 37 reads "Purgative medicines agree ill with persons in good health." Hellebore, which many of us have never had occasion to prescribe, played an important part in ancient Greek medicine. We find it in IV 16 "Hellebore is dangerous to persons whose besh is sound, for it induces convulsions" and V 1, "a spasm from taking hellebore is of a fatal nature", but IV 15 "When you wish the hellebore to act more, move the body, and when to stop let the patient get sleep and rest."

Bleeding, of course, was much in use, and the advice in VI 47 "Persons who are benefitted by venesection or purging, should be bled or purged in spring", was widely observed until late in the last century. The same advice, without the purging was repeated in VII 53. The rules about purging are extensive. IV 5 says "About the time of the dog-days, and before it the administration of purgatives is unsuitable." Adams tells us

that this rule was followed by all the Greek and Arab physicians. According to Galen, it is fighting against nature to determine inwardly by purgative medicine, while the heat is determining outwardly. Even now I think we are not agreed upon the advice in I 24 "Use purgative medicines sparingly in acute diseases and at the commencement, and not without circumspection"

Aphorisms dealing with surgical problems are numerous and interesting, but I shall give only a few. VI 6 "A severe wound of the bladder, of the brain, of the heart, of the diaphragm, of the small intestines, of the stomach, and of the liver, is deadly" Galen points out that the word "deadly" is often used in the sense of "very dangerous" VII 14 says that "stupor or delirium from a blow on the head is bad" VI 8 "In dropsical persons, ulcers forming on the body are not easily healed" VI 38 "It is better not to apply any treatment in cases of occult cancer (meaning either not ulcerated or deep-seated), for if treated the patients die quickly, but if not treated, they hold out a long time" IV. 79 "In those cases where there is a sandy sediment in the urine, there is calculus in the bladder or kidneys". Galen added the words "or kidneys", saying they were not mentioned in the copies of the Aphorisms then in use. A belief still encountered is shown in VI 12 "When a person has been cured of chronic hemorrhoids, unless one be left, there is danger of dropsy or phthisis supervening"

Gynecology and obstetrics are freely represented. V 50 "If you wish to procure menses in a woman, apply as

large a cupping instrument as possible to the breasts" V 42 "A woman with child, if it be a male, has a good color, but if a female, she has a bad color", raises many questions about the accuracy of observation, while V 38 clearly goes back to the very old belief in the uterus as a two-chambered organ, it reads "If, in a woman pregnant with twins, either of her breasts lose its fulness, she will part with one of her children; and if it is the right breast which becomes slender, it will be the male child, or if the left, the female" By the time of Galen the error had been recognized V 49 is interesting ethnologically, because Adams tells us the practice was popular in the North of Scotland in his time, about one hundred years ago. The Aphorism says "To procure the expulsion of the secundines, apply a sternutatory, and shut the nostrils and mouth"

The First Aphorism is in two sentences, which I shall consider in the reverse order, for the second sentence forms a fitting introduction to the technical aphorisms that follow. It reads, in Adams' translation "The physician must not only be prepared to do what is right himself, but also to make the patient, the attendants, and externals cooperate" This reveals a wise and experienced physician who knew well one of the most important parts of the practice of his art. He knew the votary of the Old Medicine, who had left his crutch and his votive offering in the Esculapian temple, he knew the solicitous relatives, from grandmother down, the fussy neighbors, with recommendations from the market place, the theater and gym-

nasium, and the advocates of all the cults, and he avoided all discussion and argument in one apodictic sentence. The beginning of the Aphorism is also, I think, best rendered in English by Adams, as follows "Life is short, and the Art long, the occasion fleeting, experience fallacious, and judgment difficult." The opening words have arrested the attention of some of the most acute minds in all the ages. Cicero, Horace, Seneca, Pliny the Elder, Juvenal, Martial, Sallust, and other Roman writers knew them. Molière used the first part of the aphorism in a medical comedy, "The Flying Doctor." Goethe quoted "Life is short, Art long" twice in the First Part of "Faust." Longfellow's use of the words in the "Psalm of Life" is well known. Daremberg, the learned medical historian said "The beginning of the Aphorisms has an incomparable majesty. It is impossible to imagine expressions so brief and so striking for describing the grandeur of Medicine and the responsibility of the physician." In the original Greek the Aphorism is even more concise than is most translations, as the Greeks omitted verbs, so that we might read "Life short, but the art long" etc. It is an interesting proof of the practical value of the Greek language that of the ten chief words in the first half of the Aphorism, seven are in daily use in English words like biology, brachycephalic, technic, macrocosm, empiricism, oxygen, and crisis, and two others are used in chemistry. It is hardly necessary to say that all medical commentators hold that "Art" means the Art of Medicine. The context makes this clear, but no medical man can object

to the more general application, as by Goethe and Longfellow.

The next phrase, "Occasion fleeting" deserves comment. The word used for occasion means not time in a general way, but "fit", "proper", "exact or critical time", "time in reference to subject". It corresponds to the Latin "opportunitas". The word for "fleeting" is literally "sharp," "pointed", "cutting", "vehement", "prompt", "fleeting".

It is easy to see from this alone the keen therapeutic sense of the author. We can understand how it was that he seized the time for opening an empyema, and we can imagine how his mind would have appreciated the exigent medicine of today, with a perforated peptic ulcer, an acute appendicitis or an empyema of the gall-bladder, a twisted pedicle, a tumor of the spine, or a meningitis. Yet the needed promptness runs a risk at present of being missed by reason of the technical details that seem necessary and that can be done more rapidly if promptness is realized as essential. I often think how applicable a certain saying attributed to Napoleon is in such cases. It is said that after an early Italian battle the opposing commander asked for an armistice in order to improve his position. Napoleon with more oratory than Grant on a similar occasion, said "No", adding "It may happen that I shall lose battles but you will never catch me losing minutes, either by overconfidence or sloth. In converting Greek into medieval Latin there were some difficulties. 'Occasio' that is, 'opportunity', 'fit time', or 'favorable time', is nearly always used by early editors for 'time'."

was used by Hugo of Siena (d 1439) in a Venice, 1498, edition (Osler Library, No 171), and in the Florence Articella of 1534. It also appears in the Van der Linden edition, Lugd Batav, 1665. "Acutum" was used for the 1498 and 1534, "praeceps" for the 1665. Praecept, "headlong", "sudden", was the adjective most frequently following "occasio", but "celeris", and "volucris", "fleet", are also used. Heurnius, 1543-1601, who edited many editions, was not satisfied with such simple language and said "Occasio momentosa & magni momenti". A few editors introduced a "nevertheless" into the phrase. English, French and German editors followed the general ideas, and we find "occasion sudden", "l'occasion echappe" (Le Clerc, 1702), "l'occasion passe vite", "l'occasion prompt a echapper", "l'occasion fugitive", and "rechte Augenblick", "Gelegenheit fluchtig", "schnell vorbeigehend", "plotzlich". Dr Eliot used "occasion instant" in the inscription for one of the Harvard Medical School buildings, an unusual word equivalent to "urgent". (See Second Epistle of Paul to Timothy, Rev vers 4 2 "be instant in season, out of season".)

The next clause, "experience fallacious", has caused more difficulty to translators than any other part, and furnishes an interesting study. "Experientia fallax" is a frequent Latin term, and can be traced back to soon after 1500, but "experimentum fallax" is older, i.e., 1498 (Hugo de Seno). While we now distinguish between "experiment" and "experience" that was not always so. The words came from "Pera", and

when we test this word by its early use, we find that it indicates such things as trial, attempt, undertaking, thing to be proved, and so makes the basis of the old and modern word empiricism. It often included attempts the outcome of which might be uncertain. So it was used for a trick, a stratagem, hence a robbery or piracy; a temptation, in ecclesiastical writing, an attempt to seduce a female, an action by sea, and so on. The qualifying adjective, translated "fallacious", means more frequently "slippery", or "likely to cause a slip, fall or hurt, insecure, doubtful, delusive, perilous, reeling, unstable".

Galen recognized the point of weakness in the phrase, and commented at considerable length, but also with some obscurity. It seems clear that he meant that therapeutic experiment is dangerous, because it may involve the life of a human being. But we must understand the position of therapeutics at the time, with its division into sects, the Methodists who relied upon theory, the Empirics, who tried experiments, and the Dogmatists, who took a middle course. Evidently the Hippocrates who objected to the routine use of hellebore was not the same who incised the empyema. In the former case he was probably right in withholding the drug, but in the latter he was trying the "dangerous experiment" of operation rather than leaving the patient to die according to rule. If the incision did not heal, and the patient had what we now recognize as a tuberculous empyema, Hippocrates might well have said "experience fallacious". Then as now, different degrees of faith in rules affected one's

practice Guy of Chauliac with Gallic keenness read that part of the aphorism, "experience fallacious and dangerous" As printing went on "experimentum periculosum" was preferred, and "experimentum fallax" rare, and "experientia periculosa" almost disappeared, reviving in 1829, while "experientia fallax" disappeared and reappeared in a similar way In the Foes-Plant edition of 1633 (Lugd.) Foes preferred "experientia fallax", while Plant chose "experientia periculosa" Heurn, who had to make matters more emphatic, introduced "empirica perichitatio periculosa" (1601, 1609, 1627, 1633) Even before the experimental age was conscious of its surroundings, the question of interpretation had to be considered, and so we find Paracelsus making a characteristic pronouncement For a copy of this I have to thank Dr W W Francis It is taken from No 177 of the Osler Catalog Except for Paracelsus specialists it would be too long to quote in full Paracelsus states that "in the beginning" there was no Theory, but only Experience "thus loosens, that constipates" "Scientia 1st nimmer Experimentum fallax das macht die Theorika medica, etc"

Dr Francis has also found an interesting comment in the "Medicina Hippocratica exponens Aphorismos Hippocratis" Auctore Johanne de Gorter Ed Prima Italica Patavii 1747 From this it seems that de Gorter distinguished between experiment and experience, and went on to say "Not every experiment is perilous, for many physicists and chemists have made many experiments, in which there was no peril But in medicine

an experiment is perilous, for the end of a rash experiment is death" Modern languages, of course, give only a reflection of the perplexities of the earlier Latin writers So we see that in Le Clerc in 1702, Dezeimeris in 1841, and Littré in 1845 "trompeuse" is used to describe "l'expérience", Daremberg put it "l'empirisme est dangereuse" The Germans began later, and followed the same lines J F C Grim, 1837 "Erfahrung trügerisch", Fuchs, 1895 "Versuch trügerisch", Kurt Sprengel, 1789 "Erfahrung misslich", J A Petschaft, 1825 "Der Versuch gefährlich"

The English translation of Sprengel of 1708 is very crude and puts the phrase "to make experiments dangerous" An early English edition, anonymous, the Preface signed "S H" London, 1610 puts it "experience uncertain". It was a refreshing variation when Francis G Benedict took President Eliot's version and made "experiment" an experiment in the modern way, not a therapeutic essay perhaps hundreds of years old, but a formal scientific procedure, gave a brilliant plea for the Aphorism as a guide "where the occasion for observation, for test or proving may exist but for a short time and the danger of not making the critical experiment at the proper time is indeed perilous" The recent discussion on "The Art and Human Nature" by Stewart R Roberts* gives eloquent testimony to the vitality of the aphorism as a guide to the Art in its clinical application

*Roberts Stewart R The Art and Human Nature New York 1922 pp 70-76

The last clause in the sentence, "judgment difficult", has come down in almost the same words in all the versions I have examined, "judicium difficile" (Lat.), "jugement difficile" (Fr.), "urtheilen schwierig" (Germ.) This is all the more remarkable since a simpler and more clinical meaning was near at hand. For the word "krisis", translated as "judgment" or "decision", involving choice or discrimina-

tion, also was used by Hippocrates for the crisis or critical stage of an illness. I find myself rejecting the latter interpretation "the crisis of a distemper", difficult, and agree with the more metaphysical interpretation given by so many others who have been puzzled and fascinated by the old but immortal medical theme "Life short, but the Art long, opportunity fleeting, experience fallacious, judgment difficult"

A Neglected Research

"MY SUGGESTION on this occasion [is] to initiate a thorough study of the problem of longevity in its special application to the medical profession. I feel strongly that a study of the lives, the habits and the recreations of, say, one thousand men of mark in the medical world for the last quarter of a century would make an extremely valuable contribution to knowledge. And this study should be amplified by research into all the more promising studies thus far made into the cause of death in the medical profession in this and other countries, with due regard to ages at death and the lessons to be learned from the countless instances of premature demise. Let guesswork and crude speculation be replaced by an authentic study of the salient facts, for it goes without saying that the nation suffers no greater social losses than that of the wasted years of life in the part of its medical men who die many years in advance of their attainable time.

"No career presents more strenuous mental effort, more exacting demands upon time, more sacrifice of means, more foregone leisure, than that of the doctor who takes his work seriously, and there are few who do not. No class of men renders a greater and more indispensable service to society than those who practice the art of medicine, in all its branches and selected specialists. Upon no group of men falls a heavier burden or a greater responsibility in peace and in war. And none has done more to advance the cause of a true civilization in which the blessing of a long life and freedom from illness and suffering is made the supreme test of its attainment on the part of an ever-increasing portion of mankind. Yet as I have shown, the evidence regarding its own health and longevity is decidedly disconcerting, while suggestive of neglect that justifies the inquiry suggested." FREDERICK L. HOFFMAN, LL.D., in *Life and Death in the Medical Profession*, 1932. The Prudential Insurance Company of America, Newark, New Jersey.

Editorial

NON-MEDICAL DISTRIBUTION OF DRUGS AND MEDICINES

The social, medical, and economic importance of the distribution and employment of drugs under other than proper medical direction is forcefully set forth in a recent publication* from The Committee on the Costs of Medical Care. In this report it is stated that the people of the United States spend each year approximately \$715,000,000 for drugs and medicines, of which only 27 per cent (\$190,000,000) is the portion expended for prescriptions, or for other purchases made with the direct advice of medical practitioners. This means that the public spends annually \$525,000,000 for self-medication in its various forms. The retail sales of home remedies account for \$165,000,000. These are usually bought without the express instruction of the medical profession, but may have been purchased at the suggestion and oftentimes with the approval of medical practitioners. The nation's bill for "patent medicines" comes to \$360,000,000. In the words of the Abstract of this publication (Number 14):

*The Costs of Medicines, The Manufacture and Distribution of Drugs and Medicines in the United States and the Services of Pharmacy in Medical Care, by C. RUFUS ROSEN, Ph.D., C.P.A., and ROBERT P. FISCHER, B.S., Ph.D., University of Chicago Press, 268 pages, April, 1932. Price in cloth, \$2.50. Abstract obtainable from The Committee on the Costs of Medical Care, 910 Seventeenth St., N.W., Washington, D.C.

"Thus a total of \$525,000,000 is spent by the American people for medicines on their own initiative to cure minor or chronic ills which seem too trivial or too frequent in occurrence to warrant a call upon a medical practitioner, and to alleviate temporarily physical or mental symptoms which may or may not be the danger signals of serious disorders." The total amount spent for drugs and medicine is roughly of the same general order of magnitude as the sum spent for the services of physicians, or for hospitalization, and represents a charge, on the average, of between \$20 and \$25 per family per year. Since such purchases are made voluntarily by people who still have their earning capacity, and are distributed throughout the year, they have not been considered a burden and have not provoked unfriendly or critical discussion.

The "drug stores" of this country receive each year \$485,000,000 from the sale of home remedies and "patent medicines." The remainder of the expenditure for self-medication goes to mail-order houses, general stores, herbalists, itinerant vendors, etc. Aspirin, and sometimes more potent anodynes and soporifics, can be obtained in many restaurants and at soda fountains not connected with drug stores. One must have a good deal of sympathy for the pharmacist in the position in which he finds himself. If he conducts his business with conscientious regard to the ethical code of his profession, which decrees that he must not assume the functions and prerogatives of a physi-

cian by attempting to diagnose a customer's condition or by prescribing medicines for him, he does so in full knowledge that he is playing to the hand of a less conscientious competitor. At a time when the standards of education and experience which must be met in order to qualify for licensure as a pharmacist are being raised in many states, the whole tendency of pharmacology, therapeutics and pharmaceutical manufacture is such as to give the pharmacist less and less opportunity to practice the science of compounding medicines. He is forced to turn to merchandising, to catering, and to the art of salesmanship in order to secure economic independence. Although fewer doctors compound and dispense remedies from their offices, there is an increasing tendency for physicians to prescribe medicines already compounded under proprietary names. Judging by the advertisements which crowd many European medical journals, this tendency has reached a level on the continent which we may earnestly hope will never be approached here.

While the better type of druggist no longer stocks patent medicines for venereal diseases and deprecates over-the-counter prescribing for them, it is common knowledge that it is in connection with this group of diseases that the most flagrant disregard for professional ethics and public welfare exists. That which is 'common knowledge' is likewise supported by thoroughly controlled investigation. In the course of a survey* of the medical aspects of so-

*Survey by F. Snow, M.D., and Warren C. Snow, M.D. Medical aspects of social hygiene in San Francisco. *J. Social Hyg.*, 1931, 8, 25-27.

cial hygiene in San Francisco, questionnaires were filled in and returned by 130 drug stores. Of these, 79 per cent reported that 1,545 patients with disorders thought to be gonorrhea and 323 with disorders thought to be syphilis had applied for advice or for remedies during the month of July, 1931. Of the 102 druggists who stated what they did for those requesting such aid, 19 per cent admitted that they furnished remedies, 10 per cent furnished remedies occasionally, but in some instances referred them to a physician or clinic, 49 per cent always referred inquirers to a physician or clinic, and 23 per cent stated that they gave no information. As a check on the answers given, investigators visited 120 such establishments and gave a vague account of symptoms leading to an inference of the presence of venereal disease. The replies received indicated that 56 per cent of the drug stores visited were willing to undertake the illegal practice of medicine by diagnosing, or by prescribing, or both. Only 31 per cent definitely refused either to diagnose or to prescribe, and advised the inquirer to go to a doctor or clinic. Similar investigations have been conducted in several other cities. In Chicago, 63 per cent of the drug stores visited made diagnoses and offered to sell remedies or to treat syphilis or gonorrhea; in New Orleans, 34 per cent, in Washington, D. C., only four per cent. In addition, 445 young men of San Francisco were interviewed casually on the street and in barber shops and pool rooms to ascertain what they would do, or advise doing, if infected with a venereal disease. Thirty-six per cent advised going to a drug store

for aid, as compared to 23 per cent who would go to a physician and 18 per cent who would go to a clinic. There were six per cent who advised going to an herbalist or similar charlatan.

The extent to which the Chinese herb doctor, whose materia medica includes weird "remedies" of animal as well as vegetable origin, flourishes along the Pacific slope is almost beyond belief. The survey to which reference has been made revealed over 75 Chinese herb shops in San Francisco and vicinity alone. It is estimated that there are more than a thousand of them in this country. During the survey 12 herbalists were visited and all offered to sell remedies to "cure" syphilis or gonorrhea. "Six out of eight herbalists to whom letters were written diagnosed one of these diseases by means of the insufficient symptoms described in the letters and 'guaranteed' to cure by correspondence. The terms ranged from \$10 to \$50."

In the current telephone directory of one of the larger cities of the state of Washington there is displayed an advertisement which reads, in part, as follows: "Wing Wo Chinese Medicine Co., established 1899. Come in no matter what your ailment. The Chinese successfully use roots, herbs, barks, and berries for every ailment of mankind." Whether such concerns can be prosecuted under medical practice acts or not, it is extremely unlikely that the telephone company would in this instance continue such advertising if proper representations were made to it

by the County and State Medical Societies.

There are a number of ways in which the practitioner can do something to lessen this distribution of drugs without proper medical supervision. Here his personal interests are in such full accord with those of public welfare that he need not feel hampered lest his activities be construed as entirely self-serving. He should lose no opportunity to keep before his clientele and the lay public the fact, so much to their advantage, that the indispositions for which they undertake self-medication may be the manifestations of serious affections which require diagnosis in their early stages if they are to be cured or controlled. He should invoke the aid of, and lend his support to, those possessed of legal authority, as well as better business bureaus, and other agencies to secure the elimination of those practicing medicine illegally or making fraudulent promises of cure. Finally, he should secure in so far as possible, the sincere cooperation of pharmacists. He can demonstrate his appreciation of the problem facing the pharmacist by refraining from being a competitive compounder of medicines himself and by prescribing in such a manner as to make use of the professional knowledge and skill of the pharmacist, rather than depending largely upon medicines already compounded and sold under proprietary names. Both economically and therapeutically the patient should benefit by such a course of action.

Abstracts

Death Rates in a Group of Insured Persons (Public Health Reports, 1932, xlvii, 437-440)

Tables which can be found in the Statistical Bulletin of January, 1932, issued by the Metropolitan Life Insurance Company, provide an index, in advance of governmental figures, of the mortality status of the general population. They present the mortality experience of the industrial department of this company, by principal causes of death, for 1931 as compared with 1911 and 1921-1930, inclusive, and for December, 1931. The rates for recent years are based on between 17,000,000 and 19,000,000 insured persons in the United States and Canada. Although this is a more or less selected group and is largely urban, the death rate is a fair indication of the trend in the general population. In recent years the general death rates in this group have been averaging about 72 per cent of the death rate for the registration area of the United States. Six diseases, tuberculosis, diphtheria, whooping cough, pneumonia, diarrheal complaints, and puerperal conditions, recorded lower mortality rates in 1931 than ever before. The rate for typhoid fever equaled the minimal figure previously attained. The mortality rate for tuberculosis dropped 57 per cent in spite of the prevailing economic conditions. This is a larger decrease than the average year-to-year decline during the preceding decade, and the rate is 65.9 per cent lower than for 1911. Mortality from diphtheria showed a drop of 24.6 per cent in one year and of 50 per cent in five years. In spite of an incipient epidemic of influenza at its beginning, the year ended with a new minimum for the death rate from this cause. The death rate for diarrheal complaints and childbirth showed a decrease of 3.3 per cent for this group as compared with 1911. Part of this decline is due to the falling birth

rate. That some of the reduction is real can be demonstrated by computing the rate on the basis of live births. New minimal death rates were recorded for accidental burns and for injuries in railroad accidents, and rates lower than those in 1930 for alcoholism and chronic nephritis. On the other hand, an increase of 7.4 per cent appeared in the death rate for cancer in 1931. While the death rate for diseases of the heart is slowly rising, the increase is found in the older ages only. Diabetes recorded a new high rate, 14.4 per cent greater than in 1930 and 61 per cent above that of 20 years ago. Here the increase is in the age group past 45 years, and particularly among women. The mortality from automobile accidents increased more than five per cent over the rate for 1930. For this cause of death there has been a rise of almost 900 per cent in 20 years, and it is estimated that not less than 34,000 people lost their lives in automobile accidents in the United States in 1931. The Bulletin upon which this article is based states that "as yet there has not been any appreciable injury to the public health from the economic conditions that have prevailed".

[Editorial Comment. As has been pointed out previously in the editorial columns of the ANNALS, the reasons why present economic conditions have not produced a recognizable deleterious effect in respect to mortality and morbidity are multiple. Even in economic depression itself there are positive and negative public health factors, the algebraic sum of which is not easily determinable. After all, study of such statistical analyses as that of the paper here abstracted, leaves the firm impression that the chief factor in lowering mortality rates has been the progress which Medicine has made in the prevention and treatment of those diseases which take their heavy toll before the middle period of life. Rising mortality rates for the so-called degenerative dis-

eases must be expected, since all must die. Life-savings at one end of the scale must be balanced by life-losses at the other, for preventive medicine can neither bestow immortality nor appreciably alter the histogenetic life limit imposed upon human protoplasm by the evolutionary processes of millions of years. Rather may we not expect that the proportion of those past middle life who will attain extreme old age will decrease, since there will be preserved to reach that group some who are intrinsically less resistant? One must view with apprehension the rapidly rising list of automobile casualties, preventable for the greater part, and yet taking an annual toll from all walks of life, including those best fitted to render significant service to the race. Our own profession pays a heavy tribute to this cause of death.]

Cirrhosis of the Liver By FRANK B. MALLORY, M.D. (New Engl. J. Med., 1932, ccvi, 1231-1239)

Among 9346 autopsies performed at the Boston City Hospital during the past 35 years there were found 550 examples of well-marked hepatic cirrhosis, an incidence of 5.88 per cent. These were classified as follows:

Alcoholic cirrhosis	270	48.90 per cent
Pigment cirrhosis	49	8.90 per cent
Healed acute yellow atrophy	46	8.36 per cent
Syphilitic cirrhosis	28	5.09 per cent
Colon bacillus cirrhosis	25	4.54 per cent
Obstructive cirrhosis	24	4.36 per cent
Obstructive and colon bacillus cirrhosis	3	0.54 per cent
Cancer cirrhosis	1	0.18 per cent
Not classified	104	18.90 per cent

It was found that healed acute yellow atrophy and syphilitic cirrhosis may occur at any age but alcoholic cirrhosis and pigment cirrhosis are practically limited to adult life and cause death at a late age, indicating that these latter lesions require many years for development. The incidences of ascites, jaundice, esophageal varix, hemorrhage and of various degrees of enlargement of the spleen are given for each

type of cirrhosis represented in the series. Enlargement of the spleen with increase in stroma elements was of frequent occurrence and is directly due to the obstruction to the flow of portal blood through the liver. Twelve examples of primary liver cell cancer were encountered. Four of these were in association with pigment cirrhosis and three each with alcoholic cirrhosis and healed acute yellow atrophy. Obstructive cirrhosis is caused by occlusion of either the hepatic or common bile duct. There results a slight to considerable sclerosis around all of the bile ducts, producing a smooth to finely granular cirrhosis which is commonly called biliary cirrhosis. The cirrhosis produced by an ascending colon bacillus cholangitis likewise involves the bile ducts and the immediately surrounding tissues. If any type of cirrhosis should be recognized as Hanot's, it would seem to be the early stage of this. [The editor has thought that diffuse congenital syphilis in an adult liver more nearly meets the conception of Hanot's cirrhosis.] It seems probable that in addition to the well-known group of toxic substances, capable of producing acute yellow atrophy of the liver, the direct action of a streptococcus must be added in considering the etiology of this important form, which is so frequently missed in clinical diagnosis. Pigment cirrhosis forms the first and most important lesion in hemochromatosis. It is characterized by the presence of two pigments in the liver cells, hemofuscin derived from hemoglobin and hemosiderin which is slowly developed from the hemofuscin. Pigment cirrhosis can be produced in rabbits, sheep and monkeys by means of chronic copper poisoning in 6 to 12 months provided the dose is large enough. In man as far as can be ascertained from clinical observations, well-marked pigment cirrhosis requires in the neighborhood of fifteen years for development. The clinical cases of chronic copper poisoning are to be found in the copper coils used in distillation apparatus or in ones made from brasses in which copper containing material has been sprayed and in occupations in which the cutting grinding and polishing of brass and bronze. As to alcoholic cirrhosis, experimental evidence is recent that it is

being the cause of this lesion. The essential histopathological lesion, hitherto not generally recognized, involves the development of minute hyaline droplets within the cytoplasm of the liver cells. These droplets fuse to form an irregular hyaline meshwork about the nuclei. There is some experimental evidence that a similar basic lesion is produced by phosphorus, so that the suggestion is made that this substance may be the cause of so-called alcoholic cirrhosis. However, the presence of phosphorus in alcoholic beverages has not been demonstrated as yet so that certain desirable links in the chain of evidence are still missing.

Auricular Fibrillation Ambulatory Treatment with Quinidine By S. A. WEISMAN, M.D. (Arch Int Med, 1932, xlix, 728-734)

This article deals with 24 patients with auricular fibrillation who were treated by the ambulatory method with quinidine sulphate in the outpatient department of the University of Minnesota. All patients were first given digitalis. If the heart is decompensated the patient is well digitalized until there is evidence that the heart is fully compensated, or nearly so. Quinidine is then given in small doses: 0.1 gm on the first day, 0.2 gm on the following day, and on the third day, 0.4 gm. For five days this dose is maintained, with 0.1 gm taken every two hours. At this point the digitalis may be reduced or discontinued. On the seventh day the dose of quinidine is increased to 1 gm per day (5 grains every two hours until three doses have been taken). Later the amount may be increased to 20, 30, or even 40 grains per day, always given in divided doses at two hour intervals. As soon as cardiac rhythm becomes regular the dose of quinidine is reduced, and a maintenance dose is established. This may be 5 grains daily, or 5 grains every other day. Normal rhythm was restored in 17 of the 24 cases treated,

that is, 70.8 per cent. Eighteen of the 24 patients were 50 years of age or over, in 14 of this group, 77 per cent, the heart was restored to normal rhythm. Regular rhythm was restored, also, in three of the remaining six. Those with hypertension seemed to respond more quickly than the rheumatic group. Two accidents occurred during treatment: one death from coronary thrombosis, and one case of hemiplegia.

A Case of Friedlander's Pneumonia By E. H. BENSLEY, B.A., M.D. (Canad Med Assoc J, 1932, xxvi, 681-684)

The patient, an adult, white male, 42 years of age, was well until three days before admission to the Montreal General Hospital. On rising in the morning, he had vomited, soon suffered from headache, and had chills, warm flushes and sweats, cough, and expectoration. The temperature ranged between 101.4° and 104.4°, and signs of consolidation appeared at the left base on the day following admission. The patient's condition became steadily worse and he died 38 hours after admission to the hospital, on the sixth day of the illness. At autopsy, the entire upper lobe of the right lung and large portions of both lobes of the left showed consolidation. From the cut surface of the solid areas, a large amount of mucinous greyish purulent material was exuded. Microscopical examination showed considerable numbers of large mononuclear cells as well as polymorphonuclear leucocytes in the alveoli. Red cells and fibrin were less prominent in the exudate than is usually true of pneumococcal pneumonia. The Friedlander's bacillus was obtained from three sources in this case—the sputum (ante mortem), ante mortem blood culture, and post mortem blood culture. A white mouse, inoculated intraperitoneally with washed sputum, yielded pure cultures of Friedlander's bacillus from the heart's blood and the peritoneal exudate.

Cancer What Everyone Should Know About It By JAMES A. TOBEY, Dr P H, Fellow, American Public Health Association, Associate Fellow, American Medical Association, Member, American Society for the Control of Cancer With introductions by JOSEPH COLT BLOODGOOD, M.D. and H. L. MENCKEN 323 pages with 17 illustrations Alfred A. Knopf, New York, 1932 Price, \$3.00

Cancer, What Everyone Should Know About It, is written, as the title indicates, particularly to inform the laity about cancer. The author has taken pains to explain all medical terms and procedures in detail. Dr. Tobey describes the nature of cancer and gives its history throughout the ages. A chapter is devoted to brief life stories of famous persons who had cancer, as the Bonaparte family, Presidents Grant and Cleveland, and many others. In giving the types and locations of cancer it is stated that cancer of the stomach is the most serious form of the disease, causing about one-third of all deaths from cancer. He believes it to be as curable as any other form when an early diagnosis is made. More frequent gastrointestinal X-ray examinations are advocated in all cases of chronic dyspepsia in the hope of reducing the mortality of cancer of the stomach.

"Danger signals of all cancers can be summarized in these words:

1. Any lump in the breast or other part of the body, especially one which begins to grow or change,

2. Any sore that does not heal particularly on the face or mouth,

3. Any unusual discharge or bleeding from any part of the body. Pain, it should be remembered, is always one of the later symptoms."

In regard to treatment

"No member of any of the healing cults outside the pale of regular medicine is capable

of giving proper treatment for cancer, and faith healing is worse than nothing." He emphasizes that there is no serum nor vaccine, no salve, plaster or paste and no chemical, except radium, which had been proven to alleviate cancer. In regard to irradiation, x-ray or radium, he states that "it cannot surpass surgery in many instances, and in others it is only a supplement to it, but in numerous cases it is an effective substitute. He gives an interesting review of the history of x-ray and radium, particularly Madame Curie's life and work. Dr. James Ewing is quoted as to the heredity of cancer, whose view, in brief, is that the hereditary influence does not convey the disease but only structural peculiarities rendering certain organs especially prone to cancer. Dr. Maude Slye's work and Dr. Warthin's cancer family are also described. The author makes it clear that contagion plays no part in the causation of cancer and repeatedly warns against quack cancer cures, telling at length of the evils of "The Great American Fraud." He advocates surgery, x-ray and radium as the only known treatment of cancer. The whole message is one of hope and cheerfulness. The author feels that cancer is largely preventable with proper knowledge, and curable if diagnosed and treated early. But how very often it is impossible to make an early diagnosis, because of inaccessibility and lack of definite findings! But to err in the direction of optimism may not be altogether a fault in a book intended for intelligent laymen.

R. C. W.

Applied Pharmacology By A. I. CLAY, M.C., M.D., F.R.C.P., F.R.S. Professor of Materia Medica and Pharmacology in the University of London, formerly Professor of Pharmacology in the University of Cambridge and Lecturer in the University of London. Published by

590 pages, 72 illustrations P Blakiston's Son and Co, Inc, Philadelphia, 1932 Price, \$4 00 net

This edition of *Applied Pharmacology* follows its predecessor after an interval of but two years. This has been necessary in order to incorporate the recent advances in therapeutics. This book differs from the purely academic presentation of Pharmacology in an effort to bridge the gap which is too often widely existent between that science and therapeutics. Thus we find the subject matter arranged, for the greater part, according to organs and systems with a view to function, rather than with regard to the origin or nature of the medicinal agents themselves. Throughout, the aim has been to present such actions of drugs as are capable of scientific demonstration. There are certain minor changes which, in the next edition, would increase the usefulness of this book. Some point is made of the relative costs of drugs, but these values are in English currency requiring the American reader to transpose to terms with which he is more familiar. It is questionable whether a chapter of but 17 pages covering all forms of radiations is worth including or even germane to the subject covered by the title. Although familiar with the work of Aub and his associates, the author seems to have missed the point (page 538) that the most effective treatment of some forms of lead poisoning is to promote lead fixation, as contrasted with lead elimination. The index has not kept up with the revision. Although the text includes a paragraph on ephedrine the index does not refer to that drug. Aside from such minor faults, this is a very useful book, well-printed and unusually free from typographical errors.

United States Army X-Ray Manual Second Edition. Rewritten and Edited by LT. COL. H. C. PETERS, MC USA. 500 pages, 224 ill. Paul B. Hoeber, Inc., New York City, 1932. Price in flexible binding \$5 00.

The second edition of this book was the joint effort of several men and was intended to cover particularly the problems of war. It is a practical manual for the World War. Some of the problems have changed

until the care of the sick of a peace time army and the service to World War veterans have given to the radiologists of the Army precisely the same problems as confront their colleagues in civil life. The chapters treated are X-ray Physics, Dangers and Protection, Laboratory Experiments, Fluoroscopy, Technic, Field Unit, Localization, Bones and Joints, Sinuses, Mastoids and Brain, Teeth and Maxillae, Thoracic Viscera, Urinary Tract, and Gastrointestinal Tract. Therapy is not considered, but in a clear and concise form there is provided an adequate description and discussion of apparatus, technic, and interpretation. Practical suggestions for safeguarding the use of x-ray apparatus and for handling radioactive substances make a valuable section. The localization of missiles and other foreign bodies is treated very completely. The mechanical structure of this manual is pleasing and practical. In addition to its special use in military service, this book is admirably adapted to the needs of those whose situation is such that they are required to do occasional roentgenologic work without the elaborate equipment of laboratories devoted exclusively to this specialty. Is it not equally true of the roentgenologist outside of the Army that "he must remember, however, that his work is valuable only in so far as he assists the physician or surgeon in arriving at correct conclusions, and that this can be accomplished only by mutual cooperation"?

Pathology for Nurses By EUGENE C. PIERCE, M.D., Pathologist and Director of the Clinical Laboratories of the West Suburban Hospital, Oak Park, Illinois, Consulting Pathologist, Chicago State Hospital. 251 pages, 65 illustrations, some in color. F. A. Davis Company, Philadelphia, 1932. Price, \$1 75.

As clearly stated in the preface, and as apparent from the text, this book is intended to provide instruction in the fundamentals of pathology, of necessity simply and briefly put, and to give detailed practical instructions for the intelligent handling of specimens required for the laboratory. In general the subject matter is fairly well chosen to meet these ends. A simply written intro-

ductory chapter explaining what is meant by normal and abnormal life, health and disease, would be of value. There are many statements in respect to detailed pathology which are open to question. Some may be the result of an unusual personal experience. It is not the experience of most pathologists, for instance, to find that "diaphragmatic hernia is not an uncommon developmental anomaly." Curiously, actinomycosis is said to be caused by a "yeast-like organism", and to be a condition "rarely occurring in this country." The chapter headings are extremely misleading, for leprosy and Hodgkin's disease are considered in the chapter headed Tuberculosis, and gonorrhea and chancroid under Syphilis. Illustrations of malignant melanoblastoma, both primary and secondary, occur in the chapter headed Benign Tumors. This book shows the results of careful proof reading and non-medical editorial supervision. The typography is excellent.

Modern General Anesthesia, A Practical Handbook By JAMES G. POE, M.D., Lecturer on General Anesthesia in the Medical and Dental Departments of Baylor University, Anesthesiologist of Baylor University Hospital of Dallas, Consulting Anesthetist to the Shriners' Hospital for Crippled Children, and Parkland Hospital, Dallas, Texas, etc. Second Edition, Completely Revised and Enlarged. 231 pages, 12 illustrations and 2 charts. F. A. Davis Company, Philadelphia, 1932. Price \$2.50.

In *Modern General Anesthesia* the author presents the subject matter in a very clear and concise manner which should make the book of great value to the student of anesthesia. At the beginning is a very complete chart (which should be redrawn for the next edition to eliminate the misspelled words) showing the zones of the third stage of ether or ether sequence anesthesia. At the end of each descriptive section is a brief, easily followed outline of the important material in the section. Throughout the book, Dr. Poe stresses important points some of which the untrained are likely to overlook. He also emphasizes the importance of standard colors for gas tanks to prevent confusion

and accidents, particularly in emergencies. The author believes that the danger of ignition during the administration of ethylene is practically the same as with ether and warns of the danger of static ignitions occurring when using ethylene or ether in fractional rebreathing since there is insufficient humidity from rebreathing to eliminate the possibility of static discharge. The same danger exists in giving ethylene intermittently for relief of labor pains. He feels that ethylene has a decided place in anesthesia. The author discusses intelligently the choice of an anesthetic and states that because of its strong likelihood of causing protoplasmic poisoning, chloroform should not be used as an anesthetic except in emergency. The non-volatile anesthetics and local and spinal anesthesia are described in detail. "Since the advent of the use of the pleasant gaseous anesthetics, every patient should be induced into anesthetic sleep as comfortably as they go to sleep in their own bed at home, and a technique that does not admit of this accomplishment has no place in modern anesthetic practice." This quotation is characteristic of the attitude of the author toward his chosen field.

R C W

Counts and Doctors By LLOYD PAUL STRAKER. xvi + 236 pages. The Macmillan Co., New York, 1932. Price \$2.00.

"Taking a leaf from the pages of preventive medicine, I have tried to explain the nature of a malpractice action, in the hope that an understanding of this malady may render those who understand it more immune to its dread ravages." Thus does the author state the purpose of the work which he has so well accomplished. For many years the general counsel for the Medical Society of the State of New York he draws upon a rich practical experience for much of the material presented. Most of the treatises on the legal aspects of the practice of medicine neglect the phase of the subject emphasized here—that is those events and policies which bring the physician into court as defendant or expert witness in an action for malpractice. An extended discussion of parts I and II of the patient-physician relationship with the legal responsibilities of the doctor

leads to the development in part III of the elements of the action for malpractice with a careful elucidation of the necessary proofs to be established by the plaintiff and the possible lines of defense which may be undertaken by the defendant. Of equal value is the explanation of the most common errors committed by physicians which expose them to malpractice suits. The simple straightforward advice herein contained can scarcely fail to be of value to those in all the branches of medicine. For those interested in the many cases quoted and cited as illustrative material, very complete and satisfactory indices are provided. This interesting and valuable book went to the fourth printing in five months. It deserves to be a medical "best seller". J C B

The Principal Nervous Pathways. Neurological Charts and Schemes with Explanatory Notes. By ANDREW THEODORE RASMUSSEN, Ph.D., Professor of Neurology, Department of Anatomy, University of Minnesota Medical School, Minneapolis.

Minn. 73 pages, 28 figures. The Macmillan Company, New York City, 1932.

As the outgrowth of an extensive teaching experience Rasmussen has prepared this monograph to aid the student in acquiring usable knowledge of the more important nervous pathways in the central nervous system. It represents a correlation and fusion of structural information (morphology) with knowledge of function, and thus it builds a dynamic conception of the nervous system. The structural diagrams are supplemented by schematic outlines embodying much of the same information. A certain element of dogmatic presentation is necessary to bridge the gaps in this field. This is inevitable, and such changes as may be made desirable by additions to our knowledge can be incorporated in the subsequent editions which are sure to be required for such a well-conceived book. While intended for the student, both undergraduate and more advanced, this should prove a valuable aid to the practitioner and a reference source not to be despised by even the professional neurologist.

College News Notes

POST-CLINICAL TOUR

Immediately following the completion of the San Francisco Clinical Session, about 125 members of the College and their families left on a Post-Convention Tour, visiting the Yosemite Valley, Los Angeles and environs, and the Grand Canyon of Arizona.

From Sunday morning, April 10, to Tuesday noon, April 12, the group were entertained in Los Angeles by members of Southern California, under the leadership of Dr Francis M Pottenger, the incoming President, and Dr Egerton L. Crispin, Governor for Southern California. Trips were arranged through Hollywood and Beverly Hills to the sea, with a visit to the beautiful Japanese home and gardens of Mr Bernheimer, overlooking Santa Monica Bay and

the Pacific Ocean. Dinner and a delightful program were given at the Uplifters' Club. Will Rogers was among the entertainers at the Club, and many members had the opportunity of meeting him personally and shaking his hand. A visit was also made to Pasadena and the California Institute of Technology where the Wind Tunnel of the Guggenheim School of Aeronautics and the Million Volt X-Ray Tube were demonstrated. Dr Pottenger acted as host to the entire group for luncheon on the lawns of the Pottenger Sanatorium in the foothills of the Sierra Madre Mountains in Monrovia. Members were also taken to the Huntington Library at San Marino, where they saw the Gutenberg Bible and the Huntington Galleries, where hang many rare and noted paintings, including the "Blue Boy." The Mission San Gabriel, one

PART OF THE POST-CLINICAL SESSION GROUP ON THE LAWN OF THE
POTTENGER SANATORIUM, MONROVIA

of the oldest of the historic Spanish Missions of early California, was also visited

Never before has such a delightful Post-Convention Tour been arranged, and the appreciation of one and all was expressed to every member of the College in Southern California, who so graciously assisted in the arrangements of the program

WILLIAM D STROUD ELECTED TREASURER OF THE COLLEGE

Following the sudden and untimely death of Dr Elmer H Funk, who was elected Treasurer of the American College of Physicians during the San Francisco Session in April, the Board of Regents have elected Dr William D Stroud, of Philadelphia, Treasurer, with duties to start at once

Dr Stroud is Associate Professor of Cardiology in the University of Pennsylvania Graduate School of Medicine, Physician-in-Chief of the Heart Clinic, Pennsylvania Hospital, a member of the staff of the Robinette Foundation of the University of Pennsylvania, Physician-in-Charge of the Children's Heart Hospital, and Cardiologist to the Bryn Mawr Hospital

ARRANGEMENTS FOR MONTREAL SESSION, 1933

The Seventeenth Annual Clinical Session of the American College of Physicians will be held in Montreal, Canada, February 6-10, 1933. The Board of Regents of the College during the San Francisco Session, specified the month of February, in accordance with the original practice of the College to meet in midwinter when there would be no conflicts with the meetings of other national bodies or of state societies. The local Committee on Arrangements at Montreal, of which Dr Jonathan C Meakins is General Chairman, selected the week of February 6 as a time that would be most suitable to the local profession, a time when the weather would probably be most settled, a time at which the winter sports are at their height, and the week preceding the meeting of the Council on Medical Education of the American College of Physicians, of which a number of the

sicians must go. The personnel of the Montreal Committees is as follows.

General Chairman

Jonathan C Meakins

Committee on Arrangements

J C Meakins, Chairman

C F Martin

E P Benoit

J E Dubé

R H M Hardisty

A T Henderson

Joseph Kaufmann

D S Lewis

E H. Mason

C F Moffatt

I M Rabinowitch

C G Sutherland

H P Wright

Committee on Clinics

J C Meakins, Chairman

C F Moffatt

I M Rabinowitch

E P Benoit

J E Dubé

H P Wright

E Dubé

Committee on Auditorium and Local Transportation

Joseph Kaufmann, Chairman

R H M Hardisty

E H Mason

Committee on Publicity

C G Sutherland } Joint

E P Benoit } Chairmen

(Additional appointments pending)

Committee on Convocation and Banquet

C F Martin } Joint

E de L Harwood } Chairmen

D S Lewis

J E Dubé

A T Henderson

Committee on Entertainment of Visiting Women

Mrs J C Meakins, Convenor

(Additional appointments pending)

President F M Pottenger appointed on May 3, 1932, the following Nominating Committee

James H Means, Boston, *Chairman*

Noble Wiley Jones, Portland

Ernest B Bradley, Lexington

Edward J G Beardsley, Philadelphia
Charles F Martin, Montreal

The above appointments are in accordance with the provision of the By-Laws, Article I, Section 3, which states that the President "shall appoint within one month after induction to office a Nominating Committee of five, composed of two members of the Board of Regents, two members of the Board of Governors, and one Fellow at large, whose duty it shall be to nominate candidates for the elective offices, Board of Regents, and Board of Governors. The selection of nominees for the Board of Governors shall be made after due consideration of suggestions of members from the respective States, Provinces or Districts which will be represented by the nominees, if elected. The list of nominees for President-Elect, and for the First, Second and Third Vice Presidents shall be submitted to all the Masters and Fellows of the College at least one month before the annual meeting, and the election of all nominees shall be by the members of the College at its annual business meeting. This does not preclude nominations made from the floor at the annual meeting itself."

Under the sponsorship of Dr A B Brower (Fellow), Dayton, Ohio, Governor of the College for the State of Ohio, a meeting and luncheon of all Ohio members of the College was held during the Ohio State Medical Association's meeting at Dayton during the first week in May. Those present decided to hold a similar meeting annually at the time of the annual meeting of the Ohio State Medical Association in the future. Among those who attended the luncheon were thirty-three Fellows and thirteen Associates.

Dr Adolph Sachs (Fellow), Omaha Nebr, Governor of the College for the State of Nebraska, was elected President of the Nebraska State Medical Association at the annual meeting of that society during the week of May 23.

Dr Homer Davis (Fellow), Genoa, Nebr, was elected a Vice President.

Cecil O Lorio (Fellow), Baton Rouge, La, was the symposiarch and contributed a

paper on "Childhood Type Tuberculosis" in a symposium on tuberculosis by the Staff of Our Lady of the Lake Sanitarium, Baton Rouge, March 23, 1932. Dr Lester J Williams (Fellow), Baton Rouge, read a paper also, his subject being "X-ray of Tuberculosis."

During the five days following the San Francisco Clinical Session, Dr Linn J Boyd (Fellow), New York City, addressed the Sophomore, Junior, and Senior classes at the University of California, was the guest speaker at Dr Kerr's Staff Conference, and addressed the San Francisco County Medical Society.

Acknowledgement is made of the receipt of gifts to the College Library of publications by members, as follows:

Dr Frederick R Barnes (Fellow), Fall River, Mass,—1 reprint,

Dr Grafton T Brown (Fellow), Washington, D C,—1 reprint,

Dr Lewis W Brown (Associate), Newark, N J,—1 reprint,

Dr I W Held (Fellow), New York, N Y,—10 reprints,

Dr Roland N Klenimer (Fellow) Lancaster, Pa,—2 reprints,

Dr Lowell L Lane (Associate), Philadelphia, Pa,—3 reprints,

Dr James Z Naurison (Fellow), Springfield, Mass,—1 reprint,

Dr Paul H Ringer (Fellow) Asheville N C,—4 reprints,

Dr Karl Rothschild (Fellow), New Brunswick, N J,—1 reprint,

Dr W E R Schottstaedt (Fellow), Fresno, Calif,—1 reprint,

Dr Leon L Solomon (Associate), Louisville, Ky,—2 reprints,

Dr Henry K Taylor (Fellow) New York, N Y,—1 reprint,

Dr Edwin Henes, Jr (Fellow) Milwaukee, Wis.—1 book "Minutes Proceedings of the Inter State Postgraduate Medical Association of North America for 1931".

Dr E A Baumgartner (Fellow), Clifton Springs, N Y—collected papers from the Clifton Springs Sanitarium and Clinic on "Studies in Tropical Sprue", bound in one volume,

Dr David W Kramer (Associate), Philadelphia, Pa—4 reprints,

Dr George B Lake (Associate), Highland Park, Ill—1 reprint,

Dr C Ray Lounsberry (Fellow), San Diego, Calif—1 reprint,

Dr V C Rowland (Fellow), Cleveland, Ohio—3 reprints,

Dr A Comingo Griffith (Fellow), Kansas City, Mo—2 books formerly the property of his father, Dr Jefferson D Griffith "A Compleat Treatise of the Gravel and Stone" by Nicholas Robinson, M D, 1723,

"A Treatise on Surgical Anatomy" by Velpeau (in two volumes), 1830

Dr Samuel H Snider (Fellow), Kansas City, Missouri, addressed the Hennepin County, Minnesota Medical Society on March 16 on "Routine Methods in the Diagnosis of Pulmonary Tuberculosis" He also addressed the Minnesota Trudeau Society that evening on the subject of "Bronchial Function in Pulmonary Tuberculosis"

Dr Grafton Tyler Brown (Fellow), Washington, D C, addressed the Atlantic County Medical Society, Atlantic City, N J, on March 11 His subject was "Seasonal Hay-Fever", with special reference to the Middle Atlantic States Dr. Samuel Barbach (Fellow) and Dr Samuel L Salasin (Fellow), both of Atlantic City, participated in the discussion

Articles by Dr Brown also appeared in the January, 1932, issue of the Journal of Allergy and in the February issue of Archives of Otolaryngology

Dr Harlow Brooks (Fellow), New York, N Y, elected President and Dr L T LeWald (Fellow), New York, N Y, was elected Treasurer of the International Medical Club of America, at the Annual Meeting, April 1, 1932

The list of the titles of the articles published

by the Hudson County Tuberculosis Hospital and Sanatorium, its staff and friends, "in recognition of the achievements and devotion to the welfare of society engendered by Dr Berthold S Pollak" (Fellow), on the occasion of the Twenty-fifth Anniversary of his medical directorship of that institution

Dr Warren Pearce (Fellow), Quincy, Ill, delivered the Chairman's address before the Medical Section of the Illinois State Medical Society meeting at Springfield, May 17-19, 1932

Dr Andrew C Ivy (Fellow), Professor of Physiology and Pharmacology, Northwestern University Medical School, Chicago, delivered the annual address before the Gorgas Medical Society of the School of Medicine, University of Alabama, May 7 His subject was "Physiologic Aspects of the Etiology, Symptoms, and Treatment of Gastroduodenal Ulcer".

Dr Edward E Cornwell (Fellow), Brooklyn, N Y, read a paper before the American Therapeutic Society at Baltimore, May 17, on "A Problem of the Circulation"

Dr David Riesman (Fellow), Philadelphia, Pa, delivered an address on "Vascular Crises" before the Evanston Branch of the Chicago Medical Society, April 7, 1932.

Dr Arthur A Shawkey (Fellow), Charleston, W Va, addressed the Hempstead Academy of Medicine, Portsmouth, Ohio, on the evening of April 11, 1932 His subject was "The Hypertonic Infant"

Dr Samuel M Feinberg (Fellow), Chicago, Ill, spoke before the Kankakee County Medical Society (Illinois), April 14, 1932, his subject being "Allergy of the Respiratory Tract".

Dr Peter Whitman Rowland (Fellow), University, Miss, at a recent meeting of the State Medical Association (Jackson, Miss, April 12) announced his forty-ninth year of continuous membership in the Association

Dr Lawrason Brown (Fellow), Saranac Lake, N Y, delivered the Hermann M Biggs Memorial Lecture at the New York Academy of Medicine on May 5, 1932 His subject was "Robert Koch and His Life Work" The Biggs lecture was established in 1925 by the widow of Dr Biggs

Dr William D Anderson (Fellow), Chattanooga, Tenn, was elected a vice president of the Tennessee State Medical Association at its annual meeting in Memphis on April 14, 1932

Dr Daniel J Glomset (Fellow), Des Moines, Iowa, was made president-elect of Medical Society of the Missouri Valley at its annual meeting in Omaha, March 29-31, 1932

Dr Alfred Henry (Associate), Indianapolis, Ind, president, National Tuberculosis Association, addressed the Illinois Tuberculosis Association at its annual meeting in Danville, Ill, on April 25, 1932. He spoke on "Our Job Now"

Dr John A Lanford (Fellow), New Orleans, La, has been made chairman of a state cancer committee organized, February 22, by Dr Sidney C Barrow in cooperation with the American Society for the Control of Cancer

Dr. Lewellys F. Barker (Fellow) Baltimore, Md., Professor Emeritus of Medicine, Johns Hopkins University School of Medicine, delivered the annual Alpha Omega Alpha lecture at Jefferson Medical College Philadelphia Pa., on March 4, 1932. His subject was "Medical and Other Conditions in Soviet Russia."

Dr Louis Hamman (Fellow) Baltimore Md, presided over the forty-ninth annual meeting of the American Climatological and Clinical Association, held at the Seaside Golf Club, Absecon N J near Atlantic City May 5-7. Among the speakers at the scientific sessions were the following fellows: Dr George R. Mott, Princeton N J, Dr J. Burnet Anderson, Jr, New York N Y, Dr Paul D. White, Princeton N J.

The annual session of the Medical Society of the District of Columbia was held, May 4-5, 1932, under the presidency of Dr. Christie.

Dr Joseph H Pratt (Fellow), Boston, Mass, was chairman of the roundtable discussion on diseases of the heart and Dr Lawrason Brown (Fellow), Saranac Lake, N Y was chairman of the roundtable discussion on diseases of the lungs

At the Thirty-Third Annual Meeting of the American Therapeutic Society, held in Baltimore, Maryland, on May 16 and 17, the following officers were elected for the coming year

President, Frank Smithies (Master), Chicago, Ill,

1st Vice-President, Julius Friedenwald (Fellow), Baltimore, Md,

2nd Vice-President, Alpheus F Jennings (Fellow), Detroit, Mich,

3rd Vice-President, Grafton Tyler Brown (Fellow), Washington, D C,

Secretary, Oscar B Hunter (Fellow), Washington, D C,

Treasurer, Alphonse McMahon (Fellow), St Louis, Mo

Dr Hugh S Cumming (Fellow), Washington, D C, early in March took the oath of office as Surgeon-General of the U S Public Health Service for the fourth time. Dr Cumming entered the Service thirty-eight years ago and has been Surgeon-General since 1920

The American Association of the History of Medicine held its annual meeting in Atlantic City, May 2, 1932, with Dr David Riesman (Fellow), Philadelphia, presiding. The following Fellows contributed to the program: Dr Carl V Weller, Ann Arbor, Mich; Dr Charles W Burr, Philadelphia, Pa; Dr William S Middleton, Madison, Wis; Dr H R M Landis, Philadelphia, Pa; Dr Leodius F Barker, Baltimore, Md

Dr Harold Swank (Fellow), Quincy, Ill, is the author of an article "The X-Ray Diagnosis of Chronic Appendicitis," which appeared in the April 1932 issue of the *Quincy Medical Bulletin*

The following is a list of the members of the American Association of the History of Medicine who attended the meeting in Atlantic City, May 2, 1932

treatment of heart disease in Philadelphia, May 16-19, inclusive. The following Philadelphia members of the College participated as shown

Dr Ross V Patterson (Fellow), dean, Jefferson Medical College,—“A Rational Plan for the Diagnosis and Treatment of Heart Affections”

Dr Edward J G Beardsley (Fellow), clinical professor of medicine, Jefferson Medical College,—“Problems Associated with Aortic Regurgitation”

Dr Elmer H Funk (Fellow), professor of materia medica, therapeutics, and clinical medicine, Jefferson Medical College,—“Acute Endocarditis”

Dr Henry K Mohler (Fellow), assistant professor of medicine, Jefferson Medical College,—“Heart Block”

Dr Edward Weiss (Fellow), associate in medicine, Jefferson Medical College,—“Congenital Heart Disease”

Dr William Egbert Robertson (Fellow), professor of theory and practice of medicine, Temple University Medical School,—“The Diagnosis of the Failing Heart Muscle”

Dr H Brooker Mills (Fellow), professor of pediatrics, Temple University Medical School, (and associates),—“Heart Disease in Children”

Dr Joseph B Wolffe (Associate), associate professor of cardiovascular diseases, Temple University Medical School,—“Coarctation of the Aorta” (with case demonstration)

Dr E B Krumbhaar (Fellow), professor of pathology, U of P Medical School,—“Demonstration of the Pathology of the Cardiovascular System”

Dr John Eiman (Fellow), pathologist, Presbyterian Hospital,—“Anatomy of the Conducting System with Demonstration of Injection of the Purkinje System and Demonstration of Injection of Coronary System”

Dr William D Stroud (Fellow), professor in cardiology, Graduate School of Medicine, U of P,—“Treatment of Cardiac Arrhythmia”

Dr James E Talley (Fellow), emeritus professor of cardiology, Graduate School

of Medicine, U of P,—“Cardiovascular Phenomena of Thyroid Disease”

Dr S Calvin Smith (Fellow), associate professor of cardiology, U of P,—“Demonstration and Discussion of Electrocardiography in Diagnosis and Treatment of Heart Disease”

Dr Charles C Wolferth (Fellow), Robinette Foundation, U of P,—“The Relation of Cardiology to General Medicine”

Dr David Riesman (Fellow), professor of clinical medicine, U of P Medical School,—“Some of the Difficulties in the Diagnosis of Mitral Stenosis”

Dr Truman Schnabel (Fellow), physician of the Philadelphia General Hospital and assistant in medicine, U of P Medical School,—“Diet and the Gastro-intestinal Tract in Relationship to Cardiovascular Disease”

Dr William H Kraemer (Fellow), Wilmington, Del, was elected president of the Alumni Association of Jefferson Medical College at the thirty-sixth annual meeting of the association, February 18

The following Fellows were also elected to office

Dr Ross V Patterson,—vice chairman,

Dr Louis H Clerf,—vice president,

Dr Harold W Jones,—treasurer

Dr Edward J G Beardsley (Fellow), Philadelphia, Pa, Governor for Eastern Pennsylvania, addressed the Bridgeport, Connecticut, Medical Association on “Practical Post-Graduate Instruction in our own offices”, May 3, 1932

Dr Daniel P Griffin (Fellow), Bridgeport, Conn, is President of the Association and at his request Dr Beardsley also spoke briefly on the objects and ideals of the American College of Physicians

Dr Hyman I Goldstein (Associate), Camden, N J, recently read a paper before the Medical Society of New Jersey, at Atlantic City, on the subject “Recent Advances in the Treatment of Some Diseases in Children”

Dr Pauline Williams (Fellow), Richmond, Va, national president of the Alpha

Epsilon Iota Fraternity of medical women, presided at the biennial convention of that organization held at Portland, Ore. June 10-12, inclusive This fraternity embraces a membership of 1,500 women physicians and women medical students, the chapters are established in twenty-two class A medical schools throughout the country

Dr Allen K Krause (Fellow), Tucson Ariz, delivered the Theodore B Sachs resident lectures in tuberculosis at the University of Illinois College of Medicine, April 18-29 This lectureship is endowed by the Chicago Tuberculosis Institute

Dr John H Peek (Fellow), Des Moines, Iowa, was re-elected President of the Iowa Tuberculosis Association at its recent annual meeting in Burlington

Dr J A Myers (Fellow), Minneapolis, Minn, addressed the Fifth Councilor District Medical Society at Boone, Iowa, April 13, on “Tuberculosis in Childhood”

The following Fellows of the College participated on the program at the sixty-fifth annual session of the Mississippi State Medical Association, April 12-14, at Jackson Miss, as indicated

Dr Lloyd Thompson, Hot Springs Ark — “Modern Renaissance of Syphilis”

Dr Allan C Eustis, New Orleans, La — “Headaches Causes and Treatment”

Dr James G Carr, Chicago, Ill — “Treatment of Cardiac and Renal Edema”

Dr Edward C Mitchell, Memphis, Tenn — “Asthma from the Viewpoint of the Pediatrician”

Dr Waller S Leathers Nashville, Tenn presented the annual oration

Dr Henry A Christman (Fellow) Boston Mass addressed the Mahoning County Medical Society, Youngstown, Ohio on April 2 its sixth annual Postgraduate Dinner “Varieties of Bright's Disease and their Management and ‘Diuretics and their Uses”

Dr Samuel A Levine (Fellow) Boston Mass also addressed the same society on “A Clinical Concept of Heart Disease”

and "Bedside Recognition and Treatment of Cardiac Irregularities"

Dr Ernest R Zemp (Fellow), Knoxville, Tenn, spoke on "Gastric Ulcer" before the ninety-ninth annual meeting of the Tennessee State Medical Association at Memphis, April 12-14

At a meeting in the Embassy of Mexico, Washington, D C, on April 5, Surgeon General Hugh S Cumming (Fellow) was appointed President of a newly organized chapter of the Pan-American Medical Association for the District of Columbia

Dr Samuel A Brown (Fellow), New York, N Y, recently resigned as Dean of New York University and Bellevue Hospital Medical College, and has been made a member of the University Council Dr Brown had been Dean for sixteen years

Dr Henry J Ullmann (Fellow), Santa Barbara, Calif, addressed the San Diego County Medical Society, May 5, on "The Work of the Cancer Commission"

Dr Walter C Alvarez (Fellow), Rochester, Minn, was one of the guest speakers at the eighty-third annual session of the Medical Association of Georgia, May 17-20, at Savannah Dr Alvarez's subject was "Practical Points in the Care of Patients with Indigestion"

Dr James H Hutton (Associate), Chicago, Ill, has been appointed Consulting Endocrinologist to the hospitals of the Illinois State Department of Public Welfare

The following Fellows of the College addressed the Medical and Chirurgical Faculty of Baltimore at its recent meeting in Baltimore, April 23-27

Dr Henry A Carter, Boston, Mass.—"The Pathology of the Therapy of Tuberculosis"

Dr L B McBrayer, Southern Pines, N C—"Studies in the Pathology of the Tuberculosis of the Lung"

"Relation of the State Board of Health to the General Practitioner"

In connection with a special four months' course in Internal Medicine held at the Harvard University Medical School, April 1 to August 1, Dr Frank Dennette Adams (Fellow), Boston, Mass, has charge, for six weeks, of a course in Internal Medicine at the Massachusetts General Hospital, which began June 20 During July, Dr. Samuel A Levine (Fellow), Boston, Mass, will conduct a course in modern diagnosis and treatment of heart disease at the Peter Bent Brigham Hospital

The following members of the College contributed to the program of the Nebraska State Medical Association, held at Lincoln, Nebr, May 24-26

Dr Ernest S Wegner (Associate), Lincoln, Nebr—"Infant Feeding",

Dr Arthur D Dunn (Fellow), Omaha, Nebr—"Cholecystography",

Dr Andrew C Ivy (Fellow), Chicago, Ill—"Physiology of Mucus Secretion with some experimental results on the prevention of Ulcer with 'Gastric Mucin'",

Dr Walter C Alvarez (Fellow), Rochester, Minn—"Practical Points in the Handling of Patients with Gastro-Intestinal Disease"

Dr. Edgar B Friedenwald (Fellow), Baltimore, Md, on May 13 addressed the Atlantic County Medical Society, Atlantic City, N J, on "Diet Problems and Therapeutics in Children"

Dr L B McBrayer (Fellow), Southern Pines, N C, was re-elected Secretary of the Medical Society of the State of North Carolina at its annual meeting on April 20

The following Fellows of the College delivered papers at the annual meeting of the National Tuberculosis Association held at Colorado Springs, June 6-9

Dr James Burns Amberson, Jr, New York, N Y—"Comparative Value of Paper and Celluloid Films for Chest Roentgenograms, Report of 1,000 Cases",

Dr Carl H Greene, Rochester, Minn—

"Treatment of Addison's Disease with Cortical Hormone of the Suprarenal Gland"

Dr Gerald B Webb (Fellow), Colorado Springs, Colo, addressed the annual dinner meeting on "Robert Koch".

Dr Roy Lyman Sexton (Associate), Washington, D C, addressed the Tippecanoe County Medical Society, May 5, at Lafayette, Ind, on "Colon Disturbances and Involvements including Endocrine Aspects"

Dr William S Middleton (Fellow), Madison, Wis, and Dr Arthur L Anderson (Fellow), Springfield, Mo, addressed the Missouri State Medical Association at Jefferson City, May 23-26, on "Syphilis of the Circulatory System" and "Value of Routine Basal Metabolism in the Examination of Patients", respectively.

Dr Louis E Viko (Fellow) was recently appointed Health Officer of Salt Lake City

Dr George G Ornstein (Fellow), New York, N Y, spoke before the Cambria County Medical Society, Cresson, Pa, May 12, on "Diagnosis and Treatment of Pulmonary Tuberculosis"

Dr Willis F Manges (Fellow), Philadelphia, Pa, delivered an address on "Relation of Sinus Infection to Pulmonary Diseases" before the Eleventh Councilor District Medical Society, May 19

"Collapse Therapy in the Treatment of Pulmonary Tuberculosis" was the subject of a paper delivered by Dr Charles H Marcy (Fellow), Pittsburgh, Pa, before the Erie County Medical Society, Erie, Pa, on May 3

Dr. Joseph H Barach (Fellow), Pittsburgh, Pa, addressed the Crawford County Medical Society, May 9, on "Focal Infection"

Dr James H Means (Fellow), Boston, Mass, was re-elected Secretary of the As-

sociation of American Physicians at its recent meeting

At the annual meeting of the American Gastro-Enterological Association, May 2, Dr Charles G Lucas (Fellow), Louisville, Ky, was reelected Secretary

Dr Arthur L Bloomfield (Fellow), San Francisco, Calif, was elected President of the American Society for Clinical Investigation, on May 2

Dr Howard T Karsner (Fellow), Cleveland, Ohio, was recently reelected Secretary of the American Association of Pathologists and Bacteriologists for the ensuing year

Dr William E Engelbach (Fellow), New York, N Y, addressed the staff of St John's Hospital, Brooklyn, May 3, on "Results of Therapy in Pituitary Disorders" On May 16, Dr Engelbach addressed the joint meeting of the Baltimore Medical Society and the American Therapeutic Society at Baltimore on "Endocrine Therapy in Disorders of the Hypophysis"

Dr Abraham M Ornstein (Fellow), Philadelphia, Pa, has been appointed Assistant Professor of Neurology in the University of Pennsylvania School of Medicine. Dr Ornstein has also been elected President of the Philadelphia Neurological Society

Dr John G Fitzgerald (Fellow), Toronto, Ont, has been appointed Dean of the University of Toronto Faculty of Medicine

Dr E J G Beardsley (Fellow) Philadelphia, Pa, as a guest speaker, addressed the Kiwanis Club of Woodbury, N J, May 12, on "The Influence of the Hospital on the Community"

Dr Ralph K Hollister (Fellow), Westville, N J was also a guest of the Club on this occasion

Dr Walter M Soper (Fellow) Princeton, Ohio was elected President of the American Society of Clinical Pathology at its recent meeting at New Orleans

Dr David W Kramer (Associate), Philadelphia, Pa, was recently appointed Visiting Physician to the Medical Staff at the St Luke's and Children's Hospitals

PERPETUAL MEMORIAL FUND
IN HONOR OF

DR JOHN B DEAVER

The Aid Association of the Philadelphia County Medical Society is establishing a special perpetual fund in honor of Dr John

B Deaver, only the income of which will be used to afford aid to needy physicians and their families. All friends of Dr Deaver are invited to participate. All money received will be placed in the Dr John B Deaver Perpetual Memorial Fund. Checks should be drawn to the order of the Aid Association of the Philadelphia County Medical Society and sent to

Dr Francis Heed Adler, Secretary,
313 So 17th Street, Philadelphia, Pa

OBITUARIES

DR ORLANDO HENDERSON PETTY

Dr Orlando Henderson Petty (Fellow), Philadelphia, Pennsylvania, an outstanding medical hero of the World War, died as the result of a self-inflicted gunshot wound, at his home on June 2, 1932. Dr Petty was born in Cadix, Ohio, in 1874, and received his academic education in that State, with his B S degree from Franklin College. He was graduated in medicine from the Jefferson Medical College of Philadelphia in 1904. Dr Petty served his internship at St Timothy's Hospital, Roxborough, Philadelphia, in which institution he later became pathologist and visiting physician.

Shortly after Dr Petty completed his internship, a latent lung lesion made itself evident and he was advised to live an open-air existence with restrictions as to physical activities. Following the enforced and unwelcome vacation, an opportunity presented itself to become associated with Dr John B Lowman, a distinguished surgeon of Johnstown, Pa., in the field of industrial surgery. After a year spent in the west Dr Petty returned to the city of Philadelphia and soon later to a general practice in

Roxborough where he became intimately associated with that great physician and medical teacher, Milton H Fussell. During this period Dr Petty became actively engaged in clinical teaching at the Jefferson Medical College, in which unremunerative and disinterested labor he continued for many years.

Dr Petty was, for a period, pathologist to the Germantown Hospital and faithfully served the City of Philadelphia as a medical inspector of its public schools.

At the time the United States entered the World War Dr Petty, in spite of excellent reasons why he should delay his military service, applied for active service and was immediately assigned to the Marine Corps. He sailed for France in August, 1917, and was soon serving in the field with the Fifth Marines, Second Division. The Corps to which Dr Petty was assigned was soon in the thick of battle and Dr Petty distinguished himself by outstanding bravery and heroism. For his conduct on the field of battle and his efficient professional services, he received the Congressional Medal of Honor, The United States Distinguished Service Cross, the Croix de Guerre

of France with palm, and the War Cross of Italy Dr Petty shared with Dr Joel T Boone the signal honor of being the only two officers of the Medical Corps to receive the Congressional Medal of Honor

Dr Petty was severely gassed during his heroic work with the wounded and spent much time in the Military Hospital as a result At the conclusion of the war Dr Petty returned to his home city a nationally acknowledged hero, but in extremely poor physical and financial condition, to take up the problems of readjustment

Without thought of self, Dr Petty began immediately and with characteristic energy and enthusiasm his undergraduate teaching and, at the same time, expended strength, that his disordered body could ill afford, in many medical, military service and other civic undertakings He was elected President of the Philadelphia County Medical Society, President of the Medical Club of Philadelphia, Commander of the Thomas Roberts Reath Post No 186 of the American Legion, National Commander of the Army and Navy Legion of Valor, and was active and interested in many similar agencies

In 1923, Dr Petty, whose medical interests had been especially with the disorders of metabolism, was elected Professor of the Diseases of Metabolism in the Graduate School of Medicine of the University of Pennsylvania where he came in contact with many graduate physicians from various parts of the world Medical articles and books from Dr Petty's pen and addresses by him stimulated a new interest in disorders of nutrition Dr Petty built at the Philadelphia General

Hospital a Department of Nutrition and headed an active service for the investigation of metabolic disorders

For a short period in 1931 Dr Petty served as Director of Public Health of Philadelphia to succeed the late Dr Andrew A Cairns, under whom Dr Petty had worked many years as Medical School Inspector

When one contemplates what Dr Orlando Henderson Petty accomplished in the twenty-eight years that he lived after receiving his medical degree and considers the handicap of persistent ill health that had never been absent, one can but wonder at the spirit, the determination and the unconquerable ambition that drove him on For many years prior to his military service, Dr Petty's life was a continual struggle to overcome a more or less active tuberculous lesion which he would never, consciously acknowledge Following the exposures and the physical and emotional stress of military life, the lung lesion became active and duodenal ulcer also developed which later was never entirely symptom free During the last months of Dr Petty's life a prostatic lesion developed that demanded surgical attention in spite of the existing serious contra-indications Although all this were not enough for one pain-racked and harassed brave man to endure, nature further restricted Dr Petty's activities by a serious painful and disabling attack of coronary occlusion Under the best conditions a physician in Dr Petty's precarious state of physical and mental health could only find a way out by taking a prolonged rest with entire freedom from physical and emotional stress and strain Dr Petty was fortunate

pressing period of our national history and the weight of all his ills and anxieties proved too great a strain. Throughout the United States are physicians whom Dr Petty has taught, with whom he has served, or with whom he has maintained friendly contacts. All these and many other admirers and friends will sincerely regret his passing. Dr Petty was a sincere, dogmatic, and conscientious teacher, perhaps, even in his end, there is a potential lesson for each of us to remember. A physician's health is his greatest asset and this, in spite of everything, he must preserve by a judicious care for his own body.

E. J. G. BEARDSLEY, M.D., F.A.C.P.,
Governor for Eastern Pennsylvania).

DR JOHN ALDEN LICHTY

Dr John Alden Lichty was born in 1866. He received the degrees of Ph.B., Ph.M., and Ph.D. from Mount Union College, and M.D. from the University of Pennsylvania School of Medicine in 1893. He also did postgraduate work at the University of Pennsylvania in pathology and diseases of the digestive system; also postgraduate work at the University of Berlin. He was associate professor of medicine, University of Pittsburgh School of Medicine from 1909 to 1923; visiting physician, Mercy Hospital, Pittsburgh, 1912 to 1923; visiting physician, Columbia Hospital, Pittsburgh, 1906 to 1923; consulting physician, Presbyterian Hospital, Pittsburgh, 1916; superintendent, Children's Sanatorium and Clinic, 1923 to the time of his death. He was

a member and ex-president, Ontario County Medical Society; member and ex-chairman of Medical Section, New York State Medical Society, member and ex-vice chairman of Medical Section, American Medical Association; ex-member and ex-chairman of Medical Section, Pennsylvania State Medical Society, member and ex-president, American Gastro-Enterological Association; member American Climatological and Clinical Association, and member American Association for Advancement of Science. Dr Lichty was also a member of the Alpha Tau Omega and Phi Beta Pi fraternities. Dr Lichty was the author of many articles published in various medical journals and was the author of the chapter on Arthritis of the Text, "Diseases of Middle Life", F. A. Davis Company, also of the chapter on Appendicitis of Tice's "Practice of Medicine".

Dr Lichty was elected a Fellow of the American College of Physicians on December 29, 1916, and, therefore, was one of the earliest members of the organization. He served in a great many capacities in the College, including, member of the Board of Regents, 1922 to 1930, Third Vice-President, 1930 to 1932. One of his greatest contributions to the College was the early organization and Chairmanship of the Credentials Committee, on which he served faithfully and painstakingly for several years. The College was very near to Dr Lichty and even after the onset of his last illness he tried to serve the College and to attend one of its annual meetings.

DR CHARLES ROLLIN GRANDY

Charles Rollin Grandy (Associate), Norfolk, Va, died, June 10, 1932, from a cerebral hemorrhage and heart disease, aged 61 years

Dr Grandy was born in Norfolk, educated at the Norfolk Academy and the Bellevue High School. He held the degrees of A B and M D from the University of Virginia, the latter having been conferred in 1892. He did post-graduate work at the University of Berlin and the University of Freiburg, Germany. He was formerly attending physician to the Norfolk Protestant Hospital and physician-in-charge of the Norfolk Tuberculosis Clinic. For many years, he was chairman of the Norfolk School Board.

Early in Dr Grandy's career, he became interested in combating tuberculosis, to which work he devoted his energy the greater part of his life. He was responsible for the first comprehensive public health law in the State of Virginia. He organized the Anti-Tuberculosis League of Norfolk, and was its first president. He served in this capacity for twenty-seven years. In recognition of his service, Norfolk dedicated its tuberculosis sanatorium last November as the Charles R Grandy Sanatorium.

Dr Grandy was an ex-president of the Norfolk County Medical Society, a member of the Seaboard Medical Association, an ex-president of the Medical Society of Virginia, a Fellow of the American Medical Association, a member of the American Association for the Advancement of Science, a member of the American Public Health As-

sociation, a member of the National Tuberculosis Association, and had been an Associate of the American College of Physicians almost from its inception.

DR NELSON GAPEN

Dr Nelson Gapen (Fellow), Washington, D C, died January 7, 1932, of mastoiditis and meningitis, aged, 53 years.

Dr Gapen was born in Washington, where he attended public school and graduated from the Georgetown University School of Medicine in 1900. He served his internship in the Garfield Memorial Hospital of Washington, and pursued various post-graduate courses thereafter at the Army Medical School, Harvard Medical School, and the University of Michigan Medical School. For a time, he was Director of the Mary Imogene Bassett Hospital, of Cooperstown, New York. During the World War, he was in the office of the Chief Surgeon, Air Service U S A, assisted in the formation of the original Medical Research Board for Aviation, and attained the rank of Colonel. At the time of his death he was Professor of Materia Medica, Pharmacology and Therapeutics in the Georgetown University School of Medicine. Dr Gapen was a member of the Medical Society of the District of Columbia, the Association of Military Surgeons, a Fellow of the American Medical Association, and had been a Fellow of the American College of Physicians since 1929.

(Furnished through the courtesy of EUGENE R WHITMORE, M D, F A C P, Washington, D C.)

DR GEORGE HENRY
SHERMAN

Dr George Henry Sherman (Associate), Detroit, Michigan, died April 19, 1932, following an operation for appendicitis, in a hospital at Melbourne, Fla., aged 74 years

Dr Sherman was a graduate of the Chicago Medical College, 1883, he had not been in practice for several years.

DR ALEXANDER BROWN
KALBAUGH

Dr Alexander Brown Kalbaugh (Associate), Westernport, Maryland, died suddenly May 15, 1932, of coronary embolism, aged 48 years

Dr Kalbaugh was a graduate of the University College of Medicine, Richmond, Va., 1907, he did postgraduate work at the University of Liverpool during 1919. During the World War he served as First Lieutenant in the Medical Corps of the Air Service at Le Bourget and Orley Air Fields, France; he also served with Charge de Assault, French Tank Corps.

Dr Kalbaugh was an ex-president of the Allegany-Garrett County Medical

Society, an ex-vice president of the Tri-State Medical Society, member of the Medical and Chirurgical Faculty of Maryland, member of the Southern Medical Association, a Fellow of the American Medical Association and had been an Associate of the American College of Physicians since 1921.

DR ARTHUR J BURRIDGE

Dr. Arthur J. Burrige (Fellow), Winnipeg, Manitoba, Canada, died March 15, 1932, aged 56 years.

Dr Burrige was born in London, Ontario, Canada; attended the public and high schools of Winnipeg, and the Manitoba Medical College, from which he graduated in 1897. For many years he was Internist to the Grace Maternity Hospital and a member of the honorary attending staff of the Winnipeg General Hospital; he was Associate Professor of Medicine on the University of Manitoba Faculty of Medicine.

Dr Burrige was a member of the Winnipeg Medical Society, the Manitoba Medical Association, and had been a Fellow of the American College of Physicians since January 30, 1920

The Relation of Lipoid Nephrosis to Nephritis*†

By E. T. BELL, M.D., Minneapolis, Minn

"NEPHROSIS" is now generally used in a broad sense to include all forms of renal disease which are regarded as degenerative in nature, in contradistinction to "nephritis" which refers to those of inflammatory origin. However, in recent clinical literature many writers use nephrosis in a restricted sense to designate "lipoid nephrosis" only.

For many years, two forms of glomerulonephritis have been recognized.

a The *azotemic type* is characterized in the advanced stage by nitrogen retention. Edema is present from time to time but is not a conspicuous feature except in the acute stage and during acute exacerbations. Hypertension is nearly always present in the chronic stage, but is often absent in mild acute cases. The degree of albuminuria varies at different times, but is generally greater during acute phases. An increased number of erythrocytes is commonly found in the urine, especially during acute stages. Fatal cases terminate in uremia, and the postmortem reveals small contracted kidneys in the chronic form. There is a definite inflammatory reaction which leads to

occlusion of the glomerular capillaries. In subacute and chronic forms, the impermeable glomeruli gradually become hyaline and their associated tubules undergo atrophy.

b The *hydropic or nephrotic type* is characterized by marked edema and severe albuminuria. Death is frequently due to intercurrent infections and not to uremia. At postmortem large fatty kidneys are found. This form of renal disease, formerly named chronic parenchymatous nephritis, is now called "lipoid nephrosis." A great many investigators believe that lipoid nephrosis may be separated into two distinct types, viz., pure lipoid nephrosis, and a mixed type.

(1) Pure lipoid nephrosis. By general agreement the outstanding clinical features of this disease are the presence of marked albuminuria and severe edema, and absence of hypertension, hematuria, and renal insufficiency. Lipemia and decrease of plasma proteins, especially of plasma albumin, are also considered essential parts of the clinical picture. The anatomical definition demands enlarged kidneys with normal glomeruli and tubules filled with lipid droplets. It is considered a degenerative disease of the tubules.

(2) The mixed type. This form was called "nephritis with nephrosis."

*From the Department of Pathology, University of Minnesota, Minneapolis, Minn.

†Presented at the San Francisco Meeting of the American College of Physicians, April 4, 1932.

tendency" by Volhard and Fahr. It is also called the nephrotic type of glomerulonephritis. The disease has all the positive features of pure lipoid nephrosis but not all of its negative characteristics. Hypertension, hematuria, or impaired renal function are demonstrable in addition to the nephrotic syndrome. There are sharp differences of opinion as to the nature of this renal disease. Many writers consider it glomerulonephritis with superimposed nephrosis, or vice versa, others regard it as a form of nephrosis, and a few believe it to be a form of glomerulonephritis. The structural changes in the kidneys have not been extensively investigated. In a limited material I found non-contracted kidneys with fatty tubules, and a definite glomerular lesion. The glomerular lesion consists chiefly of thickening of the capillary basement membrane with narrowing of the capillary lumens, but there is a variable amount of endothelial proliferation.

A number of investigators attempt to make a sharp distinction between pure lipoid nephrosis and the mixed type. Some rigidly exclude from the "pure" group every case in which there is at any time during the course of the disease an elevation of blood pressure, an abnormal number of erythrocytes in the urine, or any impairment of renal function. If the onset follows an acute infection it is considered a mixed type. Other writers are more liberal and add to the group of pure nephroses cases that show minor deviations such as hypertension, a slight impairment of function, or a slight excretion of erythrocytes in the urine.

In a review of a few published re-

ports which conform to the rigid definition as outlined above. The more thoroughly the patient is studied, the more frequently some minor deviation is demonstrated; yet there are a few cases which conform to the rigid definition. It is obviously inconsistent to exclude thoroughly studied cases which show minor deviations, and to include cases with incomplete data that show nothing inconsistent with pure nephrosis. In his recent review, Leiter, 1931, seems to accept as pure nephrosis cases without complete clinical study when the pathological report stated that the glomeruli were normal.

THE CLINICAL PHENOMENA OF LIP- OID NEPHROSIS

Age Incidence. According to the published reports, lipoid nephrosis occurs more frequently in children than in adults, and it comprises a larger percentage of the nephritides in the former than in the latter. Clausen, 1925, observed 125 cases of nephritis in children, of which 102 were classed as hemorrhagic (glomerular) and 23 as parenchymatous (lipoid nephrosis). In general, the age distribution corresponds to that of glomerulonephritis.

Onset. The symptom that brings the patient to the physician is usually edema, but there is often a prodromal period of weakness, loss of appetite, and general malaise which precedes the onset of edema. Schwarz and Kohn, 1922, considered the absence of preceding infection an important feature of the disease. Blackfan, 1926, found an initial acute infection in only two of fourteen cases. He contrasts nephrosis with acute glomerulonephritis in this respect. Van Slyke, 1930, found

three out of nine cases in which infection seemed to play a rôle. However, other writers do not consider the absence of preceding infection a distinctive feature. Davison and Salinger, 1927, stated that the onset may be with or without a preceding infection. The initial infection is usually in the upper respiratory tract. Aldrich, 1926, found that three of seven cases of nephrosis were preceded by a cold and that colds often cause exacerbations. Lyttle and Rosenberg, 1929, found a history of infection in six out of eight patients. They consider persistent or recurrent infection the chief cause of chronicity. Apparently there is a history of preceding infection less frequently in nephrosis than in acute glomerulonephritis, but there is no sound reason for excluding a case from this group because it follows an acute infection.

Hematuria All investigators who regard nephrosis as distinct from glomerulonephritis are agreed that no case with hematuria should be classed as pure nephrosis, although the majority would accept in this group cases with a slight increase of erythrocytes in the urine. Obviously the presence of a few erythrocytes does not exclude nephrosis, since Addis has shown that the urine of normal individuals commonly contains a few red cells. In the mixed type an increase of erythrocytes or even a gross hematuria is occasionally seen, but not as frequently as in acute glomerulonephritis. These differences with respect to hematuria indicate that the glomerular lesion of nephrosis is somewhat different from that of glomerulonephritis.

Albuminuria Severe albuminuria is

an essential feature of nephrosis. During the active periods of the disease large quantities of protein are excreted daily in the urine, but during remissions the amount becomes much less, and the urine may even become normal. The urinary protein is about 85 to 90 per cent albumin and the rest chiefly globulin (Van Slyke, Geil). As the albuminuria continues, the plasma proteins decrease. Corresponding with the greater loss of albumin in the urine there is a much greater decrease of plasma albumin than of globulin. It is highly probable that this depletion of the blood proteins is the basic disturbance in nephrosis which gives rise to the distinctive clinical features that set it apart as a special type of nephritis.

There is no doubt that the urinary proteins are derived from the plasma proteins. This is indicated by the high proportion of albumin in the urine and the corresponding decrease of plasma albumin. The plasma proteins are excreted by the kidneys.

Does this excretion take place through the tubules or through the glomeruli? In instances of severe albuminuria microscopic sections of the kidneys show the capsular spaces distended with protein precipitated by the fixing reagent. This can hardly be interpreted as a reflux from the tubules since it is too widespread and uniform, and it is occasionally seen in the capsular space when there is none in the adjoining part of the tubule. Bierer, 1931, has shown that chloride injections cause albuminuria in glomerular fish, but not in those with glomerular kidneys. The evidence is incon-

vincing that protein is excreted through the glomerular capillaries

Is the excretion due to injury of the glomerular capillaries, or to alterations in the plasma proteins themselves? Since normal kidneys excrete foreign protein readily, it is conceivable that the plasma proteins may be so altered by toxic substances that they are treated by the kidney as foreign protein. This seems to be what Epstein had in mind when he called nephrosis "albuminuric diabetes." This theory is supported by Andrews, Thomas and Welker, 1929, who consider albuminuria "a detoxicating mechanism for eliminating poisonous products of protein metabolism" and not primarily due to disease of the kidneys. They believe that the normal plasma proteins are so altered by combination with toxic substances that they behave as foreign proteins. According to this view it is not necessary to assume an injury of the glomerular capillaries.

But this theory is highly improbable. There are many forms of albuminuria which must be ascribed entirely to capillary injury. Simple passive congestion of one kidney causes albuminuria of the affected organ only. When the renal artery is clamped for from 30 to 60 minutes and then released a severe albuminuria results from the temporary ischemia. The urine from the other kidney is normal. Orthostatic and bedotic albuminuria depend upon circulatory disturbances in the kidney. In glomerulonephritis and the mixed type of lipoid nephrosis there is considerable evidence of capillary injury. In the light of all this it is not necessary to im-

buminuria of pure lipoid nephrosis. Furthermore, Hewitt, 1929, has shown that purified plasma and urine albumin in nephrosis and nephritis exhibit a corresponding rotatory power indicating that they are identical. The evidence is fairly convincing that the albuminuria of both types of lipoid nephrosis is due to injury of the glomerular capillaries, even though one may be unwilling to accept the anatomical evidences of such injury.

The albuminuria of nephrosis is not different from that of glomerulonephritis except that it is often more severe and more frequently cyclic in character. Severe albuminuria is frequently seen in acute glomerulonephritis and in active chronic glomerulonephritis. The amount of albumin in the urine tends to decrease as the kidneys become contracted, probably because the capillary surface available for filtration decreases. The protein is decreased by the same factors that reduce the crystalloids.

Edema. Marked edema is an essential feature of nephrosis. It is a prominent initial symptom and often the most important cause of the patient's discomfort. Like albuminuria, it is intense in the active stages and slight or absent in the remissions. Edema is by no means peculiar to nephrosis. It occurs in glomerulonephritis, eclampsia, and amyloid disease of the kidneys. It is sometimes severe in acute and subacute glomerulonephritis, but is usually not prominent in the chronic stage. It tends to decrease as renal insufficiency develops, but some edema is usually present at times in the late stages. Renal disease with severe edema may be lipoid nephrosis,

acute or subacute glomerulonephritis, or amyloid disease of the kidneys. When severe renal edema is present, one may safely conclude that the kidneys are not contracted, but the exact structural changes cannot be inferred with certainty.

Epstein has shown that one of the most important causes of renal edema is the decrease of the plasma proteins, which lowers the osmotic pressure of the blood and causes an increased flow of fluid from the blood into the tissues. Edema usually occurs when the total protein falls below five per cent, or the albumin below two per cent, and it is nearly always present when the albumin falls below one per cent. The loss of plasma albumin lowers the osmotic pressure much more than the loss of a corresponding percentage of globulin, since the molecules of the former are much smaller. Edema may be produced experimentally by repeated bleeding of an animal until the plasma protein falls to a low level (Leiter, Barker and Kirk, Kumpf). There is no loss of albumin in the urine in this experiment. The kidneys remain normal.

The decrease of plasma protein is, however, not the only factor in renal edema. In acute glomerulonephritis edema develops before the plasma proteins have decreased. Also in lipoid nephrosis edema may develop or disappear while the plasma protein level remains unchanged. It is influenced by the fluid and salt intake and by intercurrent infections.

It is widely believed that renal edema is due to disease of the tubules. This is evidently the opinion of those who speak of "tubular nephritis" and

"nephritis with a nephrotic tendency". It is supposed that a nephrotic element (tubular injury) is superimposed on an inflammatory glomerular lesion. But there is no evidence to support this theory. The renal disease in which tubular injury is most severe, viz., bichloride of mercury nephrosis, shows no edema at all or only a trace. In chronic glomerulonephritis, in which edema is usually not conspicuous, the tubular injury is much more extensive than it is in lipoid nephrosis. A majority of the tubules are in various stages of atrophy, and the persistent ones show the same accumulations of lipoid and hyaline granules as are seen in lipoid nephrosis. Fahr states that the tubular injury in nephrosis may proceed to necrosis of the tubule and subsequent atrophy of its glomerulus. In the preparations which I have studied, however, the only lesion which leads to destruction of a tubule is closure of the capillaries of its associated glomerulus. The functional disturbances in "tubular nephritis" are due to escape of plasma proteins through the glomeruli.

Decrease of Plasma Proteins. The loss of protein in the urine (albuminuria) soon leads to depletion of the plasma proteins. Albumin is decreased more than globulin since it is excreted in much greater quantity. Possibly the smaller albumin molecules escape through the glomerular capillaries more readily than the larger globulin molecules. When the total plasma protein is low the globulin exceeds the albumin because less globulin is excreted and because globulin is more rapidly regenerated than albumin. The retention of protein decreases to a limited

been discussed above. It is possible that depletion of the plasma proteins is also responsible for lipemia and other systemic disturbances in lipoid nephrosis. Decrease of plasma proteins is not peculiar to pure lipoid nephrosis. It occurs also in the nephrotic type of glomerulonephritis (Fahr and Swanson, 1926, and Linder, Lundsgaard and Van Slyke, 1924) and in amyloid renal disease. The occurrence of this phenomenon in lobar pneumonia is not understood.

Lipemia An increase of fats in the blood is usually found in lipoid nephrosis. The degree of lipemia is very variable but corresponds in a general way with the intensity of edema and albuminuria. Kumpf, 1931, produced lipemia as well as edema in rabbits by repeated bleedings—a result which suggests that depletion of the plasma proteins is a causal factor in lipemia. The greater part of the fat in the blood is neutral fat. Lipemia occurs also in glomerulonephritis when albuminuria and edema are conspicuous, but it disappears as the disease progresses toward uremia.

Hypertension Hypertension is considered peculiar to nephritis and incompatible with pure nephrosis. When it is associated with a clinical picture otherwise typical of lipoid nephrosis, the disease is considered a mixed type or lipoid nephritis. It is supposed that nephrosis has been superimposed on nephritis, or vice versa. Difficulties arise in the diagnosis of cases with moderate or slight elevations of blood pressure. The blood pressure may be normal on admission and rise later, or it may first become elevated and then fall for a few days.

of life. Occasionally the blood pressure remains at normal levels for several months, and then gradually becomes definitely high. Are cases of this type pure nephrosis or the mixed form? There are many borderline cases in which the distinction between pure and mixed lipoid nephrosis on the basis of blood pressure becomes somewhat arbitrary.

The elevation of blood pressure in nephritis is probably due to increased resistance to the flow of blood through the kidneys. Increased resistance may be caused by spastic or organic narrowing of the arterioles, or by obstruction of the glomerular circulation. In lipoid nephrosis with hypertension there is seldom any disease of the arterioles, but the glomerular capillaries are definitely narrowed by thickening of the basement membrane, and by endothelial increase. In a previous publication, 1929, I have described and illustrated this lesion.

Renal Insufficiency The absence of evidence of renal insufficiency is an essential part of the concept of pure nephrosis. Even a slight nitrogen retention in the terminal stages is sufficient to exclude the case from the group of pure nephroses, according to the views of many writers. But some impairment of renal function is often demonstrable in nephrosis without hypertension if the function is studied thoroughly in the terminal stages. Van Slyke found a definite decrease of function, as measured by the urea clearance test, in eight of ten cases of "degenerative renal disease." Most of these were instances of lipoid nephrosis without hypertension. Three of his patients died typical uremic

deaths Schreyogg, 1931, includes as "genuine nephrosis" three patients in whom the non-protein nitrogen was at times 70 to 75 mgm per 100 cc of blood. If one excludes from pure nephrosis all cases with any impairment of renal function, one is more apt to exclude a case that has been studied thoroughly than one with incomplete data. A single determination of blood urea nitrogen does not establish the status of renal function.

A number of investigators report instances of typical pure nephrosis which later develop the features of glomerulonephritis, viz., nitrogen retention, uremia, hypertension. Shapiro, 1930, reported a pure nephrosis that later developed pool concentration (1007 to 1010), low phenolsulphonphthalein excretion (two per cent), and slight nitrogen retention. The blood pressure was never elevated. Contracted kidneys were found post-mortem. Lyttle and Rosenberg, 1929, cite a pure nephrosis in a boy eleven years old, which within two months became typical acute glomerulonephritis with hypertension and nitrogen retention. Other instances in which the clinical picture shifted from nephrosis to nephritis are reported by Mason, 1926, and Christian, 1929. It is, therefore, well established that the clinical picture of pure lipoid nephrosis may pass over into that of typical glomerulonephritis.

Contracted Kidneys from Nephrosis
Fahr believes that nephrosis may progress into a contracted kidney. Mackay and Johnston, 1930, and Ehrlich, 1930, describe a case of nephrosis of 17 years duration. There was no nitrogen retention and no hypertension but a

definite impairment of renal function was indicated by the low phenolsulphonphthalein output. Death was due to peritonitis. The kidneys were greatly enlarged (300 gm each) and fatty, and about half of the glomeruli showed various stages of hyaline degeneration. Ehrlich considers tubular degeneration the primary lesion.

Clinical Course Nephrosis with definite hypertension or renal insufficiency, i.e., the mixed type, may progress to uremia, but death usually results from infection or some other cause before the blood metabolites have reached the uremic level. Nephrosis of pure type, or with only minor deviations from this clinical picture, rarely ends in uremia. Some cases recover after a duration of months or years. The disease is cyclic in character, periods of albuminuria and edema alternating with remissions during which the patient is greatly improved. The mortality is higher than in acute glomerulonephritis, and death is usually due to infections, the most frequent of which is pneumococcal or streptococcal peritonitis. Erysipelas is next in frequency.

The Role of Infection It was stated above that many authors are unwilling to admit that pure lipoid nephrosis may have its onset following an infection, their objections being based in part at least upon the theory that the disease is not of infectious origin. The onset following an infectious process is admittedly infrequent, but it can hardly be doubted that it occurs occasionally. All writers are in agreement that low resistance to infection is characteristic of the disease. Colds and sore throat often cause the symptoms

ance of edema and albuminuria in a patient temporarily free from these symptoms. Peritonitis is a frequent complication not only as a terminal infection but at any time during the course of the disease (Schwarz and Kohn, 1926, Eckstein, 1926). It may persist for a long time, and the patient may survive one or more attacks. The organisms found in the ascitic fluid are usually pneumococci, but often streptococci.

Of great interest are the remarkable observations of Schwarz and Kohn, 1926, that a bacteremia is present from time to time in nephrosis. They observed this in six out of nine patients studied. Such persistent infections as these authors describe suggest that infection may play a primary rôle in lipoid nephrosis. Since infection frequently causes a recurrence of the disease, why may it not be responsible for the first attack?

PATHOLOGICAL ANATOMY

In both types of lipoid nephrosis the kidneys are large and yellowish, and their external surfaces are smooth. The tubules are filled with lipoid droplets. There are no essential differences in the tubular lesions in the two forms of nephrosis. In nephrosis of mixed type the glomerular lesions are convincing and easily recognized. (Figures 1, 2, 3). In sections stained with hematoxylin and eosin it is seen that the cellular walls are thick and somewhat foamy in appearance but the increase in endothelial nuclei is not impressive. With the iron-haematein stain it is seen that the capillary walls are thickened and the endothelial nuclei are prominent in the membrane.

In some instances there are a great many endothelial nuclei, but usually the increase is not prominent. When death occurs, as it usually does, before the disease has progressed to definite renal insufficiency, this is the usual microscopic picture. It differs from typical chronic glomerulonephritis in that there is little or no tubular atrophy and that the glomerular lesion is chiefly a thickening of the capillary basement membrane. However, when the disease has progressed to uremia, a great many hyaline glomeruli with atrophic tubules are seen. A study of the different stages in the formation of a hyaline glomerulus shows convincingly that the hyaline condition is brought about by a progressive thickening of the capillary basement membrane. The lesion is clearly primary in the glomerulus since it is prominent there before the tubule begins to undergo atrophy. A moderately contracted kidney may develop from the mixed type of lipoid nephrosis. It differs from the contracted kidney of typical glomerulonephritis in that the hyaline glomeruli arise chiefly from thickening of the capillary basement membrane and not from endothelial proliferation as in the latter. However, in typical glomerulonephritis some of the glomeruli are obliterated in the same way as in nephrosis.

In pure lipoid nephrosis, as well as in instances with only minor deviations from this picture, most authors describe the glomeruli as normal. This observation has been made so frequently that normal glomeruli are now generally considered as an essential feature of lipoid nephrosis, and there is a tendency on the part of some au-

thors to exclude instances with abnormal glomeruli from this group Wohlbach and Blackfan, 1929, found slight glomerular lesions in their cases but attributed them to the associated peritonitis

The idea that the glomeruli are entirely normal in pure nephrosis began with Fahr, 1914. However, Fahr later modified his view somewhat. In his article in the Henke-Lubarsch Handbuch, 1925, he describes and illustrates very striking glomerular lesions in a case which shows nothing inconsistent clinically with pure nephrosis. His

illustrations are made from sections stained with hematoxylin and eosin but they evidently represent hyaline thickenings of the basement membrane such as I have described, 1929. Fahr at first attributed the glomerular lesions to tubular disease, but later he stated that the glomerular lesion is primary. He insists, however, that the glomerular lesion is degenerative (glomerulonephrosis) and distinct from glomerulonephritis, and he believes that glomerulonephrosis may lead to tubular atrophy and a contracted kidney. Evidently Fahr still believes that nephrosis

FIG. 1. Hydropic or nephrotic type of chronic glomerulonephritis. The tubules are large and pale and the external surfaces are smooth. Note that the tubules are dilated and somewhat atrophic. The glomeruli are not collapsed and there is no increase in size of them. The glomerular capillaries are very small in some lobules and very large in others. There are no hyaline glomeruli. Hematoxylin-eosin.

is a degenerative disease, but he apparently no longer maintains that the nephrotic contracted kidney results from tubular degeneration.

Aschoff, 1927, stated that there are glomerular as well as tubular lesions in lipid nephrosis, but gives no detailed observations

In 1929, I made a detailed histological study of the glomeruli of four cases of nephrosis which showed only minor variations from the clinical picture of pure lipid nephrosis. These showed increase of endothelial cells or irregular thickenings of the basement membrane. It has been objected, how-

ever, that my cases were not examples of pure nephrosis. Since that time I have had the opportunity of studying three cases of nephrosis which fulfill the most rigid requirements of the pure type. Two of these cases were kindly furnished me by Dr Klemperer of New York City. In one of these the glomeruli showed a marked irregular thickening of the basement membrane and a definite increase in the size of the endothelial cells. The lesion is more pronounced than in the four cases published by me in 1929. In Dr Klemperer's second case there is no definite increase of endothelial cells,

FIG. 2. A glomerulus from the preceding case. Azocarmine stain. Note the irregular thickening of the capillary basement membrane. The glomerular epithelium is normal. There is no increase of endothelial nuclei. The narrowing and irregularity of the capillary lumen is due to thickening of the capillary basement membrane.

and the changes in the basement membrane are only slight. The third case, furnished me through the courtesy of Dr. Amberg of the Mayo Clinic, shows patchy thickenings of the capillary basement but no increase of endothelial cells.

It must be admitted, therefore, that there are instances of lipoid nephrosis in which the anatomical evidence of injury to the glomerular capillaries is only slight and perhaps not convincing. It is highly probable, however, that if the various investigators would use a stain that demonstrates the capillary

basement membrane the reports of normal glomeruli would be much fewer.

Wolbach and Blackfan observed slight inflammatory changes in the glomeruli in nephrosis, but attributed them to the associated peritonitis. This interpretation cannot be disproved, yet there is evidence of disturbed glomerular function before the development of peritonitis. Also, the glomerulitis that one occasionally finds with peritonitis usually shows many polymorphonuclear and mononuclear leucocytes.

FIG. 3. Hydropic or nephrotic type of chronic glomerulonephritis. Dense hyaline capsulae. There are many hyaline glomeruli with atrophic tubules. High magnification of a glomerulus. Azocarmine stain. Note the extreme thickening of the capillary basement membrane with narrowing and occlusion of the capillary lumen. The thickened basement membrane shows numerous fenestrations.

ETIOLOGY AND PATHOGENESIS OF NEPHROSIS

(a) *Extra-renal Origin* At the present time a majority of authors subscribe to the view that the primary cause of nephrosis is some metabolic disorder. Because of the lipemia and the fatty infiltration of the renal tubules some believe that the primary disturbance is in fat metabolism. Others, impressed by the great loss of plasma protein, believe that the basic trouble is in protein metabolism, or that it is due to toxic alterations of the plasma proteins which lead to their excretion by the kidney. The changes in the kidneys are considered secondary to the metabolic disorder; and it is contended that the renal lesion is not severe enough to produce such widespread disturbances. It is also maintained that patients with nephrosis have a very low resistance to infection and readily develop nephritis as a secondary complication.

In preceding paragraphs strong evidence has been cited, indicating that the plasma proteins are identical with the urine proteins and that they are not altered in any way. We can explain the excretion of protein only on the assumption of injury of the glomerular capillaries, even in instances where there are no histologic evidences of injury. The excessive loss of plasma protein may well be responsible for the various manifestations of lipoid nephrosis. It is, no doubt, largely responsible for the edema, and Kumpf, 1931, has shown that repeated bleeding of the glomerular capillaries leads to the formation of lipoid nephrosis.

The interpretation of the primary cause of nephrosis is still upon

anatomical evidence. No other organ shows alterations of structure or function consistently. The tubules are filled with lipid droplets, and plasma proteins escape through the glomerular capillaries. But there are two theories as to the nature of the renal lesion.

One group of authors maintains that it is a degenerative lesion affecting only the tubules. Others admit that the glomeruli may be involved, but consider the glomerular lesion degenerative in character and distinct from glomerulonephritis (Fahr). A few consider it a form of glomerulonephritis.

The theory that the disease is limited to the tubules has very little in its favor. The protein escapes from the glomeruli. The tubules are filled with lipid droplets but they are less involved than in glomerulonephritis. When the tubules undergo atrophy it is a result of obstruction of their associated glomeruli. They do not become necrotic. It is difficult to believe that so mild a tubular injury could produce the clinical phenomena of nephrosis.

The theory that the glomerular injury is degenerative and not inflammatory in nature cannot be dismissed lightly. The chief structural change is thickening of the capillary basement membrane—a lesion that is also found in eclampsia (Bell, 1931) and in primary hypertension (McGregor, 1930). Whether this is interpreted as inflammatory or degenerative depends upon how inflammation is defined. An increase of endothelial nuclei is often found in both types of lipoid nephrosis. It is much less marked than the endothelial proliferation of typical

glomerulonephritis, but it is presumably an inflammatory reaction in both instances

The theory that lipoid nephrosis is a distinct entity meets with great difficulties in explaining the nature of the mixed type which is generally admitted to be a form of glomerulonephritis. The advocates of this theory have no difficulty in superimposing nephrosis on nephritis, or nephritis on nephrosis. They are not in agreement as to whether nephrosis is the main disease or the appendix, although the basic conception is radically different. Volhard and Fahr considered nephritis the main disease and nephrosis the appendix, but most of their followers have reversed the sequence apparently without realizing the radical departure from Volhard and Fahr's conception.

Edema is a general feature of nephritis. There is no logical basis for the assumption that every nephritis with edema has a nephrotic component. On the other hand, it is equally difficult to believe that almost all cases of nephrosis have a nephritic component. The nephritic appendix may be a slight hematuria, a temporary hypertension, or a moderate functional impairment, or one or more of these symptoms may be pronounced. The nephrotic syndrome is too closely connected with nephritis to be an independent entity.

The theory that lipoid nephrosis is a form of glomerulonephritis is based upon both clinical and anatomical evidence. Clinically there is the gradual blending of pure nephrosis with nephrotic glomerulonephritis. If one uses delicate functional tests it is difficult to find a case without some impairment of renal function (Van Slyke). An initial clinical picture of nephrosis

may pass over into that of nephritis. One is rarely certain of the diagnosis of pure nephrosis during the life of the patient. On the anatomical side, there is evidence of alterations of the walls of the glomerular capillaries in some instances of pure nephrosis and in all well-defined examples of the mixed type. The glomerular lesions are of the same type in both forms of nephrosis, but are much less pronounced in those that correspond to or approach the pure type. The lesions in the glomeruli are not identical with those of typical glomerulonephritis, since in nephrosis thickening of the basement membrane is usually more conspicuous than endothelial proliferation, but one often finds glomeruli with thick basement membranes in typical glomerulonephritis.

It is reasonable to suppose that the glomerular capillaries are first injured by some toxic substance of bacterial origin. When no reaction occurs in the capillaries, the phenomena of nephrosis develop, but when a reaction occurs (thickening of the basement membrane, endothelial proliferation) the symptoms considered characteristic of nephritis develop. When only a little reaction occurs, the patient presents slight variations from the picture of pure nephrosis. When the lesion progresses to the point of complete obstruction of the capillaries the glomerulus becomes hyaline, its tubule undergoes atrophy, and a form of contracted kidney develops.

It is possible that the toxic substance responsible for the capillary injury is somewhat different in nephrosis and nephritis. Pneumococcus seems to play a more important role in nephrosis.

It is widely believed that infection is not the primary cause of nephrosis since the onset is usually not preceded by an infectious process, yet there is abundant evidence that relapses are caused by infection. Randerath reported two cases in which severe infection preceded the renal symptoms, and Schwarz and Kohn have shown that bacteriemia occurs from time to time during the course of the disease. It has been shown that peritonitis may last for several months, causing a persistence of symptoms. In certain instances, at least, latent infection appears to be a primary cause of the renal symptoms and not merely a secondary factor.

SUMMARY

Two forms of chronic glomerulonephritis are recognized: an azotemic type characterized by nitrogen retention, and an hydropic or nephrotic type characterized by marked edema and albuminuria. There are numerous transitions between these groups clinically. In the nephrotic type the kidneys are usually large and fatty, while in the azotemic type they are commonly contracted.

The hydropic type, now called lipid nephrosis, is often subdivided into pure lipid nephrosis and a mixed type (nephritis with a nephrotic component). The pure differs from the mixed type in the absence of hematuria, hypertension, and impaired kidney function.

When the rough and repeated studies of the case have rarely seen a case that corresponds to the clinical definition of pure lipid nephrosis, it is probable that the pure type is a distinct entity.

Edema is a general feature of nephritis. There is no basis for the belief that every nephritis with edema has a nephrotic component.

If nephrosis be a distinct entity, nearly all cases of nephrosis have a nephritic component.

In well-defined instances of the mixed type of lipid nephrosis there is a marked thickening of the capillary basement membrane in the glomeruli and a variable amount of endothelial proliferation. Lesions of this type, but much less pronounced, are found in some instances of pure nephrosis as well as in nephrosis with slight variations from the pure type.

The theory is proposed that the primary disturbance in both nephrosis and nephritis is an injury of the glomerular capillaries by some toxic substance. If little or no reaction occurs in the capillaries the clinical picture of pure nephrosis develops; a moderate reaction produces some of the symptoms assigned to nephritis, viz., hematuria, hypertension, impaired kidney function, a marked reaction gives the clinical picture of nephritis.

The clinical picture depends in large measure on the character of the injury in the glomerular capillaries. When they are open and allow albumin to escape in large quantities, nephrosis develops. When they are narrowed or occluded, there is not much loss of albumin but hypertension and nitrogenous waste.

Lipoid nephrosis is not a distinct entity but a form of glomerulonephritis.

This investigation was supported by a grant from the Ella Sachs Plotz Foundation.

The Occurrence of Cystinuria in Healthy Young Men and Women*†

By HOWARD B LEWIS, Ph D, *Ann Arbor, Michigan*

CYSTINURIA has been considered a relatively rare error of metabolism. Since the report of the first cystine calculus of the urinary tract by Wollaston in 1810, the number of observed cases has been surprisingly small. Kretschmer,¹ in a review of the occurrence of cystine calculi written in 1916, was able to find reports of only 107 cases of cystine calculi in a period of more than a century since Wollaston's original observation. The present author has reviewed elsewhere² the literature since 1920 and has summarized 71 cases of cystinuria, although calculus formation had not been observed in all of these.

Cystinuria in the past has usually been diagnosed by microscopic examination of the urine, the presence of the typical hexagonal plates of cystine crystals in a urinary sediment can hardly escape detection particularly if these are present in considerable numbers. The diagnosis of cystinuria has usually been made in connection with the examination of urines of patients presenting symptoms of renal colic or calculi of the genito-urinary tract. Cystinuria uncomplicated by calculus formation has been detected almost en-

tirely by examinations of the urine of relatives of patients who have been compelled to seek surgical aid for the removal of calculi.

It seems probable that cystinuria uncomplicated by calculi may occur more frequently than is usually believed. Garrod³ states that Simon encountered one cystine sediment in 15,000 urines examined, and Primavera, one in 20,000. Sondern⁴ observed cystinuria in four urines of 35,000 specimens examined. It has been stated that only "2½ per cent of cystinurics develop stone, but the figure is probably high, on account of the large number of unrecognized cases of cystinuria".⁵ Since, as already stated, cystinuria has been diagnosed almost invariably in connection with the presence of calculi, the basis of such an estimate is not clear to the present author.

In view of the interest in the familial and genetic relationships of cystinuria and in view of the paucity of data concerning the frequency of cystinuria uncomplicated by calculus formation, it has seemed of value to report the results of a systematic chemical examination of more than 10,000 urines of young men and women, college students for the most part, for the presence of cystine. It is hoped that the

*From the Department of Physiological Chemistry, University of Michigan.

†Received for publication March 26, 1932.

present report, by demonstrating the feasibility of routine chemical examination of urine for cystine, may stimulate further work by others. Only when more data concerning the incidence and genetic relationships of cystinuria are available will a more perfect understanding of this anomaly, which presents so many surgical and medical problems, be made possible.

In recent years, two chemical tests for cystine which are simple and capable of clinical application have been suggested. The first and simpler of these is the cyanide-nitroprusside test, which has been used as a test for cystine for some years, but which does not appear to have been applied to the detection of cystine in urine extensively. This test depends upon the fact that cystine may be reduced to its sulfhydryl derivative, cysteine, by sodium cyanide and that cysteine, in the presence of sodium cyanide gives a brilliant magenta color with sodium nitroprusside. Bland⁶ has recently advocated the clinical use of this test in routine examination of urine, especially in cases of renal colic. We have carried out this test as follows: To 5 cc. of urine, 2 cc. of a 5 per cent sodium cyanide solution are added and the reaction is allowed to proceed for 10 minutes. A few drops (usually 5 drops delivered from a serological pipette of 1 or 2 cc. capacity) of a 5 per cent solution of sodium nitroprusside are added and thorough mixing is secured. Both nitroprusside and sodium cyanide should be freshly prepared. Normal urines have a pale pink color, while cystinuric urines give a very faint pink color. The color is ob-

tained. Protein, if present in the urine, should be removed before testing, this can best be accomplished by heat coagulation and removal of the precipitate by filtration.

The color developed is similar to that obtained in the well known nitroprusside test for creatinine (Weyl) or acetone (Legal). However color production with these substances is obtained only in the presence of a stronger alkali, as sodium hydroxide. The cyanide-nitroprusside reaction is not specific for cystine or cysteine, but is given by any compound containing the sulfhydryl group ($-SH$) or by any compound which on reduction by cyanide is capable of yielding this sulfhydryl group.

A second *more specific* but less simply performed test is the naphthoquinonesulfonic acid test of Sullivan.⁷ We have carried out this test according to the directions of Sullivan. To 5 cc. of urine, 2 cc. of a *freshly prepared* 5 per cent aqueous solution of sodium cyanide are added; the solution is thoroughly mixed and the reduction is allowed to proceed for 10 minutes at room temperature (20° — $25^{\circ}C$). One cc. of a *freshly prepared* 0.5 per cent aqueous solution of 1,2-naphthoquinone-4-sodium sulfonate* is added, the contents of the tubes are carefully mixed, and immediately 5 cc. of a 10 per cent solution of anhydrous sodium sulfite** in 0.5 N sodium hydroxide are added. The solutions are mixed and the reaction is allowed to proceed for 30 minutes at room

*This may be obtained from the Eastman Kodak Company, Rochester, New York.

**We have found Merck's C. P. (anhydrous) sodium sulfite satisfactory.

temperature After the addition of 1 c c of a 2 per cent solution of sodium hydrosulfite ($\text{Na}_2\text{S}_2\text{O}_4$) in 0.5 N sodium hydroxide, a *pure red color* is obtained if cystine is present With other sulfur compounds and many other biologically important substances (amino acids, carbohydrates, acetone, etc.), a yellow color is obtained According to the extensive studies of Sullivan this reaction is more specific for cystine (or cysteine) than any of the other tests proposed

In our experience with parallel tests in which both of these reactions were carried out, a negative cyanide-nitroprusside reaction has never been observed in a urine with which the Sullivan reaction was positive Occasionally a weakly positive cyanide-nitroprusside reaction has been observed in a urine which showed a negative Sullivan test We would recommend therefore that the simpler cyanide-nitroprusside test be used in routine examinations of urine for the presence of cystine, but that all urines which show a positive reaction with this test should also be tested by the reaction of Sullivan A positive Sullivan test in the light of our present knowledge is definite evidence of the presence of cystine

Most of the samples of urine examined were obtained in connection with the medical examinations given to entering students at the University of Michigan in the fall of 1929, 1930 and 1931 We wish to express our appreciation of the cooperation of the members of the University Health Service, Dr W G Forsythe and Dr Margaret Bell, both at the time of the fall examinations and during later follow-up examinations Through the courtesy of Dr Glenadine Snow and Professor Perry Brundage it was possible

to examine urines of about 1100 students at the Michigan State Normal College in the fall of 1930 and with the cooperation of Professor D L Randall we were able to examine 106 urines collected from male students at Albion College in the fall of 1929

The urines of a total of 10534 students have been examined (6253 men 4281 women) We believe that the analysis of these data affords trustworthy information concerning the incidence of cystinuria in healthy individuals of the age group which includes the average student In almost every case in which positive tests for cystine were obtained, additional samples were examined at frequent intervals We have thus been able to study a considerable number of the group at intervals over a period of 30 months

The results may be summarized as follows In this series we have observed four individuals (three men and one woman) in whose urines cystine crystals have usually been present These urines presented the typical picture of cystinuria, have given strongly positive cyanide-nitroprusside and Sullivan tests, and, as shown later in the tables, the percentage of urinary organic sulfur was distinctly higher than normal, a characteristic of cystinuria In addition 14 individuals have been examined repeatedly in whose urines strongly positive tests by both cystine reactions were regularly obtained although cystine crystals have never been present in the urine* We consider this group as definitely cystinuric as the first and smaller group In some of these 18 individuals have we been

*In one individual B C (T-1) c III, cystine was isolated from the urine

able to obtain any history of the occurrence of calculi

The urines of a third group of 11 individuals have consistently shown weak tests for cystine by both the cyanide-nitroprusside and Sullivan reactions and in many of these urines the percentages of organic sulfur of the urine have been found to vary only slightly from the normal values. The urines of still a fourth group of 11 individuals have given occasional weakly positive color tests, particularly by the cyanide-nitroprusside reaction; but the sulfur distributions of these urines have been normal. There seems little doubt that cystinuria, in the sense of the excretion of abnormal amounts of the amino acid in the urine, may be of more common occurrence than is to be inferred from the reports of the finding of cystine calculi or cystine crystals in the urine.

In a further study of the first two groups, the distribution of urinary sul-

fur was determined in some instances. Under normal conditions, cystine arising from the catabolism of protein, either exogenous or endogenous, is oxidized almost completely and the sulfur present in the cystine molecule, oxidized to sulfuric acid, is excreted by the kidneys as sulfate sulfur. A small part of the total sulfur excreted in the urine is present as organic ("neutral") or unoxidized sulfur. There exists in normal urine a trace only of cystine. In the metabolic error, cystinuria, on the other hand, a very considerable part of the cystine formed in catabolism escapes oxidation and is excreted as such by the kidneys. Since the sulfur of the cystine molecule is in the unoxidized form (organic sulfur), a marked rise in the excretion of organic sulfur is observed as a characteristic of cystinuric urine.

In table I are presented studies of the distribution of the sulfur of normal urines for comparison. It will be ob-

served that the organic sulfur comprises much less than 20 per cent of the total sulfur excreted, in most cases less than 15 per cent. In marked contrast to these values obtained for normal urines are the results of similar studies of individuals whose urine as indicated by positive Sullivan and cyanide-nitroprusside tests contained cystine (tables II and III). Values for organic sulfur as high as 40 per cent of the total sulfur excreted are commonly found and in a few individuals only does the percentage of organic sulfur fall below 20 per cent.

Particularly interesting are the results of the studies with S P presented in table II*. This subject was 17 years of age when first observed and

*In tables II and III, unless otherwise indicated, the quantitative estimations of cystine were made by the colorimetric method of Looney

has never failed to show marked cystinuria in about 25 examinations of the urine extending over a period of 18 months. Not only is the excretion of cystine very marked, but abundant cystine crystals have been present uniformly in the urine, particularly on standing. Figure 1 is a microphotograph of sediment from such a urine. This photograph was made from crystals obtained without centrifugation by means of a pipette from a urine about 30 minutes after the sample was voided. The sediment is shown to be almost pure cystine.

Despite this abundant excretion of cystine, no history of colic of the urinary tract or other indication of calculus formation has been obtained. The urine of an older brother of the patient has been examined for cystine with negative results. The analyses in the table include both 24 hour urines

¹Figures in parentheses indicate cystine present in sediment. This amount should be added to give the total daily cystine excretion.

²Urine of the three hour periods are morning urines, usually 8 45-11 45 A.M.

³Cystine determined by modified Okuda method.

⁴Night urine, 12 15 8 15 A.M.

and those excreted in shorter periods. The organic sulfur in urines collected over the shorter periods (three hours) appears to be higher than that of the 24 hour samples. This is undoubtedly due to the fact that much of the organic sulfur is not determined in the urines collected over the longer periods, since in these urines cystine, as shown in the tables, separates out and is not determined in the sulfur partition of the filtered urines.

Subject B C J (table III) is a boy of 11 years, who has uniformly shown large numbers of cystine crystals in the urine. An elder sister of this boy was operated upon for removal of cystine calculi and was definitely cystinuric.⁸ Repeated examinations of the urines of the father, mother, younger brother and four other sisters of the subject have failed to show cystinuria.

The urine of subject F P (table III) has always given strongly positive tests for cystine by both the Sullivan and cyanide-nitroprusside tests but in only one examination has the presence of cystine crystals in the urinary sediment been observed. This subject undoubtedly would not be recognized as a cystinuric on the basis of the usual examinations of the *urinary sediment*, but both *chemical tests* for cystine and the percentage of *urinary organic sulfur* indicate definitely a marked cystinuria. The case of H H (table III) is similar. In three examinations large numbers of cystine crystals were found in the urinary sediment, but the most recent examination of the urine failed to reveal cystine crystals. Despite this, the condition of cystinuria still persisted as is shown both by the intense Sullivan reaction given by the urine and by the high percentage of organic sul-

fur (44.1 per cent), a figure slightly higher than that previously observed in a study of this case.

The studies here reported serve to emphasize the fact that failure to detect cystine microscopically in the urinary sediment is not an adequate criterion of the absence of cystinuria. In clinical reports of cystinuria, the statement is frequently made that cystinuria is intermittent or that the cystinuria has ceased after operative removal of calculi. Reference is occasionally made to cystine calculi without cystinuria. These statements are based on the failure to detect cystine in the urine microscopically or on inadequate chemical tests for cystine. We have studied a case in which cystine calculi were removed at operation, but in which the presence of cystine crystals in the urinary sediment was detected microscopically in only one specimen of the urine.⁴ However, the urines at all times showed the presence of considerable amounts of cystine on *chemical examination*. Undoubtedly this case would have been cited in the past as an illustration of the cessation of cystinuria after operative removal of calculi.

Since chemical tests which are sufficiently simple to be adapted to clinical use, are now available for the detection of cystine, it is urged that each case of cystinuria and cystine calculus be studied carefully by the use of *chemical methods*. It is hoped that the data here presented may stimulate further study of this interesting but imperfectly understood error or metabolic. Only by carefully conducted study can we arrive at an adequate understanding of this disturbance of metabolism.

Effects of the Administration of Glucose and Insulin on the Glycogen Content of Normal and Experimental Damaged Livers*†

By T L ALTHAUSEN, M D , *San Francisco, California*

THE glycogen of the liver has a far reaching influence on the well-being of the body. Not only is the metabolism of carbohydrates, fats, and probably proteins disturbed when hepatic glycogen is drastically diminished, but the liver and the entire organism become more susceptible to toxic influences causing functional or organic damage. The glycogen content of the liver is reduced in diffuse injuries to this organ. This is true both of experimental animals after such procedures as administration of hepatic poisons or ligation of the common bile duct and of human beings suffering from diseases of the liver. A virtual disappearance of hepatic glycogen has been established in cases of acute yellow atrophy of the liver by Umber¹ and by Kimura.²

Evidence has accumulated to show that the amount of glycogen found in the liver at any given time represents the balance between continuous building up and release of this substance as glucose rather than the extent of its storage, analogous to that of fat. This

new conception is shifting the emphasis from a deficiency of glycogen to the underlying disturbance in carbohydrate metabolism of which glycogen, although representing only one link, is a very useful indicator. It is interesting that in experimental injury of the liver, simultaneously with the decrease in glycogen, there is an influx of fat with increased formation of intermediary substance, e.g., ketone bodies.³ Parallel with this goes a lowering of the blood sugar level and other disturbances of blood sugar regulation.⁴

From the point of view of clinical medicine it is important whether the faulty metabolism seen in diseases of the liver and expressed in a low hepatic glycogen can be favorably influenced by therapeutic measures. With this object oral and intravenous administration of glucose has been practiced for years, especially in cases of delayed chloroform poisoning and in acute yellow atrophy of the liver. Since the advent of insulin this hormone has been used in conjunction with glucose in many forms of hepatic disease.

Numerous reports of favorable curative or symptomatic results with the insulin-glucose therapy have emanated largely from German and French clinics regarding cases of acute yellow atrophy of the liver, especially

*Presented at the San Francisco Meeting of the American College of Physicians, April 5, 1932.

†From the Department of Medicine, University of California Medical School, San Francisco.

jaundice, arsenical hepatitis, cirrhosis of the liver, lues of the liver, acute phosphorus poisoning, cholecystitis, and carcinoma of the liver⁵⁻¹⁴ As basis of this therapy the authors to whom reference has been made invariably mentioned an increase in the glycogen content of the liver after administration of insulin and glucose Since in the literature there are no data on the behavior of glycogen in damaged livers, this assumption rests on an analogy with certain observations on normal animals Only one medical writer, Ravdin,¹⁵ on theoretical grounds advises caution regarding the use of insulin in hepatic diseases

THE EFFECT OF GLUCOSE AND INSULIN ON THE GLYCOGEN OF THE NORMAL LIVER

It is a mooted question whether insulin favors the deposition of hepatic glycogen in the non-diabetic animal Depending on experimental conditions increase, no change, or decrease in the glycogen of the liver after insulin and glucose have been reported by different investigators the majority of whom performed no comparative experiments with glucose alone

Among the authors who report such control experiments Macleod¹⁶ found that the addition of insulin retarded the deposition of glycogen after glucose in fasted animals with a low initial glycogen content of the liver In animals with an abundance of hepatic glycogen the amount actually reduced after insulin was small in spite of the addition of glucose Corn and Corn¹⁷ found no change in the glycogen content of the liver after insulin and glucose in the normal rat

From a complete balance sheet for ingested sugar they calculated that in the experiment without insulin three times as much of the given glucose was deposited in the form of glycogen as in the experiment with insulin.

Finally, Rubino, Varela and Collazo,¹⁸ who studied the hepatic glycogen in a series of rabbits over a period of twenty-four hours, found that after insulin and glucose there was a sharp rise in glycogen at the two-hour period followed by a rapid decline which ended in a level below that at the beginning of the experiment. On the other hand the animals which received only glucose exhibited an increased glycogen content of the liver throughout the twenty-four hours of observation

An explanation for such a decreased deposition of glycogen was offered by the Coris¹⁹ who found that under the influence of insulin more carbohydrate was oxidized leaving less to be deposited as glycogen When they increased the amount of glucose given to the insulinized animals to the point where their blood sugar was maintained on the same level as that of the animals which had received glucose alone, the same amount of glycogen was found in the livers in both groups According to this evidence the amount of glycogen deposited in livers of normal animals is a function of the height of the blood sugar.

In our experiments rabbits were given 0.5 units of insulin plus 2.5 gm of glucose per kgm of body weight and sacrificed three hours later for glycogen determinations* In normal animals there was an average increase of

*Laboratory methods and protocols are available on request.

hepatic glycogen from 5.8 per cent before to 8.5 per cent after the administration of insulin and glucose—a gain of 50 per cent

In order to test the effect of insulin and glucose on rabbits with a low glycogen content of the liver, comparable to that in animals with diffuse hepatic damage, they were starved for three days prior to the experiment. The hepatic glycogen, which was thus reduced to an average of 0.7 per cent, rose three hours after insulin and glucose to 2.3 per cent—an increase of 200 per cent

As a check on the preceding experiment the hepatic glycogen of a number of rabbits was reduced by administration of thyroxin. Each animal received subcutaneously over a period of five days a total dose of 7.7 mg. of this hormone per kgm. of body weight. These rabbits had an average of 0.65 per cent of glucose in the liver before, and 2.62 per cent after, receiving insulin and glucose—an addition of 300 per cent. A total of eighteen rabbits was used for these three experiments, the results of which are summarized in chart 1

From data of the quoted writers and the above figures, two conclusions are justified. (1) In normal animals insulin plus glucose decreases the glycogen content of the liver when this is high, effects at least a temporary moderate increase when the glycogen is neither high nor low, and stimulates a relatively large deposition when it is low. (2) Administration of glucose in equal amounts without insulin results in a greater increase of hepatic glycogen

THE EFFECT OF GLUCOSE AND INSULIN ON THE GLYCOGEN OF THE DAMAGED LIVER

In order to ascertain the action of insulin plus glucose on the experimentally injured liver, glycogen determinations were performed on four groups of rabbits. Animals in the first group received a single large dose of phosphorus, sufficient to cause death in about twenty-four hours. The experiments were carried out fourteen hours after the injection of the poison when the glycogen content of the liver was still relatively high. The average hepatic glycogen in this group was 4.7 per cent before and 1.66 per cent after the administration of insulin and glucose—a loss of 65 per cent

Rabbits in the second group were given daily small doses of phosphorus and the experiments were performed at a stage of poisoning when epinephrin ceased to produce a hyperglycemic blood sugar curve. This usually occurred after nine to twelve injections. The initial glycogen content of the liver in this group was quite low, averaging 1 per cent. Following insulin and glucose the hepatic glycogen was found to be further diminished to an average of 0.38 per cent—a reduction of 60 per cent. (Identical results were obtained in two rabbits with experimental cirrhosis of the liver due to manganese.)

In the third group the animals were given single large doses of chloroform to which about half of the animals succumbed during the first two days. The surviving rabbits were followed with the modified glucose tolerance test and the epinephrin test. The glycogen experiments were performed about ten

CHART 1. Glycogen content of the liver in normal, fasting, and thyroxin treated rabbits before (black columns), and after (cross-hatched columns), administration of insulin to two or three animals.

days following the poisoning after the hyperglycemic response to epinephrin had returned to normal and the glucose tolerance was normal or increased, probably due to active regeneration of the liver. The glycogen in these rabbits was 25 per cent before, and increased to 45 per cent after and glucose tolerance was 1.8 per cent. The

results of these three experiments are shown in chart 2.

In a fourth group rabbits were given small daily doses of phosphorus, and glucose alone was administered on the tenth day. Unfortunately a severe winter had caused widespread coccidiosis among rabbits in California so that most animals obtainable had a few hepatic lesions due to this infection, which appreciably lowered their resistance to any affecting the liver and caused a greater variability of the

glycogen content Since this work will be repeated at a more favorable time it is sufficient to mention here that the average hepatic glycogen was twice as high in the rabbits which were sacrificed after having received glucose. Glycogen determinations were made in thirty-two rabbits belonging to these four groups

The reduction of hepatic glycogen after insulin and glucose in rabbits subjected to phosphorus poisoning is unlike the already mentioned lessened deposition of this substance in the Coris' normal animals. In their case the blood sugar of the insulinized animals was lower than that of the controls. In our case the blood sugar of the poisoned rabbits due to reduced sugar tolerance was higher than that of the normal controls. As shown in a previous paper⁴ the average blood sugar of

six rabbits computed from blood sugar curves over three hours after administration of insulin and glucose was 126 mg per cent before phosphorus injections were begun, and 140 mg per cent at the stage where glycogen determinations were made

Nor can the diminution in glycogen after insulin and glucose be explained on the bases of von Noorden and Isaac's theory of glycogen formation²⁰. According to this theory glycogenesis in the liver is dependent upon the existing supply of glycogen from which energy for the polymerization of glucose is derived through its transformation into lactic acid. In our experiments we see that a relatively high hepatic glycogen in acute phosphorus poisoning fails to prevent a decrease in glycogen. On the other hand a low glycogen content of the normal liver

CHART 2 Glycogen content of the liver in rabbits poisoned with phosphorus, and chloroform before (black columns), and after (cross hatched columns), administration of insulin and glucose. The narrow, unshaded portion of each column indicates the glycogen content in each group of animals

does not hinder accumulation of this substance as seen from the experiments with fasting and with thyroxin medication

The probable explanation of the decrease in glycogen of the damaged liver lies in the fact emphasized by Macleod²¹ that insulin in non-diabetic animals "distorts the whole of metabolism by overstimulating certain phases of it. The excess causes some parts of the metabolic machinery to go too quickly or too slowly for other parts upon which it has no influence. Such disorganization may lead to the accumulation of intermediary products of metabolism having a detrimental influence on the working of the machine as a whole." Such a disturbance of the metabolic equilibrium would be even more marked in animals with injury of the liver. In these animals the insufficiency of hepatic parenchyma is evidently such that they fail to compensate for greater glycogenolysis due to insulin by increased glycogenogenesis in spite of an excess of glucose in the blood.

That the liver under the conditions of our experiments still retains its power of glycogenogenesis is shown by the presence of some hepatic glycogen in every examined animal. To this can be added an increase in hepatic glycogen after administration of glucose which is to be seen in rabbits subjected to chronic phorus poisoning.

In rabbits recovering from chloroform poisoning the glycogen content of the liver is still low in spite of a normal blood glucose. Structural rearrangement of the liver tissue to a normal condition requires time and the glycogen content of the liver is not yet normal at the time when the structural changes are still in progress.

crease in hepatic glycogen which, however, did not exceed the limits of experimental error, and therefore can be considered only as indicating that there was no rise in glycogen content. This, the last abnormality of carbohydrate metabolism to disappear during convalescence from chloroform poisoning, is explained by the work of Doljanski²² with cultures of hepatic tissue. This author showed that active proliferation of hepatic cells in vitro is antagonistic to glycogen accumulation, but that these cells could be made to fill with glycogen by artificially slowing their growth. The same is evidently true of a rapidly regenerating liver in vivo.

THE PLACE OF INSULIN IN THE THERAPY OF HEPATIC DISEASES

Having seen that insulin reduces the deposition of glycogen in the liver of normal animals and actually decreases the already small original amount of glycogen in the experimentally damaged liver in spite of administration of glucose, we are confronted with the question to what extent this knowledge can be applied to hepatic diseases in man. In answering this question two considerations are of importance. The first is the essentially uniform character of hepatic injury whether induced in experimental animals or spontaneously occurring in human beings. This conception, as discussed elsewhere,²³ is supported by microscopic evidence and by observations on the metabolic activity of the liver.

The second consideration is the similarity between the lesions of phorus and of delayed chloroform poisoning on one side, and subacute

yellow atrophy and catarrhal jaundice on the other. Incidentally it is in the last two diseases that the insulin-glucose therapy is being particularly advocated. For these reasons it is felt that the obtained data on the behavior of glycogen in experimentally injured livers have a bearing on diseases of the liver in man.

Let us turn now from the subject of hepatic glycogen to other evidence in favor of a beneficial action of insulin in diseases of the liver. Passing up such vague and unsupported statements as "stimulation of biological and fermentative processes of the liver", by insulin, we see that Bloch³ gave concrete evidence that insulin affects derangements of lipoid metabolism. He found that administration of insulin served to lower the abnormally high level of total lipoids in the blood of patients with diffuse hepatic disease and caused a sharp drop in ketone bodies lasting for two to three hours. At the end of this period the ketone bodies, especially beta-oxybutyric acid, returned to, or exceeded, the original high level. These phenomena which Bloch associated with an assumed increase in hepatic glycogen probably are due to the opposite process of increased glycogenolysis as indicated by our glycogen determinations. Such an interpretation is also favored by this author's own observations that administration of glucose had a similar but a more prolonged effect on the lipemia and ketosis of his patients. The ultimate increase of ketone bodies after insulin would according to this interpretation, be explained by a diminished output of glucose from the liver during the time necessary for a reaccumulation of glycogen up to the

amount characteristic of the functional equilibrium of the liver in a given patient.

Whatever the explanation the significant fact is that as regards the metabolism of fats glucose accomplishes at least as much as insulin. In addition it is known from clinical observations that administration of glucose reduces prolonged coagulation time in jaundice¹⁵ and exercises a protective action against delayed chloroform poisoning.

On the experimental side it has been shown that injections of glucose prolong the lives of animals in induced uremia and diminish the severity of lesions caused by intraperitoneal administration of trypsin, by photodynamic injury, and by a number of hepatic poisons.²⁴ Finally, Raydin demonstrated increased regeneration of hepatic parenchyma due to glucose in animals with obstructive jaundice after release of the ligature of the common bile duct.

In this connection it may well be asked whether the reported beneficial effects of the insulin-glucose therapy in diseases of the liver are not accomplished by glucose and perhaps in spite of insulin. At any rate the present experimental and clinical evidence does not warrant the use of insulin in hepatic diseases unless there is a co-existent diabetes mellitus.

SUMMARY

1. In normal animals fed glucose the injection of insulin decreases the amount of glycogen deposited in the liver. The relative increase in hepatic glycogen is inversely proportional to that at the beginning of the experiment and in animals with a high initial glycogen content of the liver the

does not hinder accumulation of this substance as seen from the experiments with fasting and with thyroxin medication

The probable explanation of the decrease in glycogen of the damaged liver lies in the fact emphasized by Macleod²¹ that insulin in non-diabetic animals "distorts the whole of metabolism by overstimulating certain phases of it. The excess causes some parts of the metabolic machinery to go too quickly or too slowly for other parts upon which it has no influence. Such disorganization may lead to the accumulation of intermediary products of metabolism having a detrimental influence on the working of the machine as a whole." Such a disturbance of the metabolic equilibrium would be even more marked in animals with injury of the liver. In these animals the insufficiency of hepatic parenchyma is evidently such that they fail to compensate for greater glycogenolysis due to insulin by increased glycogenogenesis in spite of an excess of glucose in the blood

That the liver under the conditions of our experiments still retains its power of glycogenogenesis is shown by the presence of some hepatic glycogen in every examined animal. To this can be added an increase in hepatic glycogen after administration of glucose without insulin in rabbits subjected to chronic phosphorus poisoning

In rabbits convalescing from chloroform poisoning the glycogen content of the liver was still low in spite of a practically complete structural regeneration and a normal response to the modified glucose tolerance and epinephrin tests. In addition after insulin and glucose there was a de-

crease in hepatic glycogen which, however, did not exceed the limit of experimental error, and therefore can be considered only as indicating that there was no rise in glycogen content. Thus, the first abnormality of carbohydrate metabolism to disappear during convalescence from chloroform poisoning, is explained by the work of Doljansk²² with cultures of hepatic tissue. This author showed that active proliferation of hepatic cells *in vitro* is antagonistic to glycogen accumulation, but that these cells could be made to fill with glycogen by artificially slowing their growth. The same is evidently true of a rapidly regenerating liver *in vivo*

THE PLACE OF INSULIN IN THE THERAPY OF HEPATIC DISEASES

Having seen that insulin reduces the deposition of glycogen in the liver of normal animals and actually decreases the already small original amount of glycogen in the experimentally damaged liver in spite of administration of glucose, we are confronted with the question to what extent this knowledge can be applied to hepatic diseases in man. In answering this question two considerations are of importance. The first is the essentially uniform character of hepatic injury whether induced in experimental animals or spontaneously occurring in human beings. This conception, as discussed elsewhere,²³ is supported by microscopic evidence and by observations on the metabolic activity of the liver

The second consideration is the similarity between the lesions of phosphorus and of delayed chloroform poisoning on one side, and subacute

yellow atrophy and catarrhal jaundice on the other. Incidentally it is in the last two diseases that the insulin-glucose therapy is being particularly advocated. For these reasons it is felt that the obtained data on the behavior of glycogen in experimentally injured livers have a bearing on diseases of the liver in man.

Let us turn now from the subject of hepatic glycogen to other evidence in favor of a beneficial action of insulin in diseases of the liver. Passing up such vague and unsupported statements as "stimulation of biological and fermentative processes of the liver", by insulin, we see that Bloch³ gave concrete evidence that insulin affects derangements of lipid metabolism. He found that administration of insulin served to lower the abnormally high level of total lipoids in the blood of patients with diffuse hepatic disease and caused a sharp drop in ketone bodies lasting for two to three hours. At the end of this period the ketone bodies, especially beta-oxybutyric acid, returned to, or exceeded, the original high level. These phenomena which Bloch associated with an assumed increase in hepatic glycogen probably are due to the opposite process of increased glycogenolysis as indicated by our glycogen determinations. Such an interpretation is also favored by this author's own observations that administration of glucose had a similar but a more prolonged effect on the hypemia and ketosis of his patients. The ultimate increase of ketone bodies after insulin would, according to this interpretation, be explained by a diminished output of glucose from the liver during the time necessary for a reaccumulation of glycogen up to the

amount characteristic of the functional equilibrium of the liver in a given patient.

Whatever the explanation the significant fact is that as regards the metabolism of fats glucose accomplishes at least as much as insulin. In addition it is known from clinical observations that administration of glucose reduces prolonged coagulation time in jaundice¹⁵ and exercises a protective action against delayed chloroform poisoning.

On the experimental side it has been shown that injections of glucose prolong the lives of animals in induced uremia and diminish the severity of lesions caused by intraperitoneal administration of trypsin, by photodynamic injury, and by a number of hepatic poisons.²⁴ Finally, Ravdin demonstrated increased regeneration of hepatic parenchyma due to glucose in animals with obstructive jaundice after release of the ligature of the common bile duct.

In this connection it may well be asked whether the reported beneficial effects of the insulin-glucose therapy in diseases of the liver are not accomplished by glucose and perhaps in spite of insulin. At any rate the present experimental and clinical evidence does not warrant the use of insulin in hepatic diseases unless there is a co-existent diabetes mellitus.

SUMMARY

1. In normal animals fed glucose the injection of insulin decreases the amount of glycogen deposited in the liver. The relative increase in hepatic glycogen is inversely proportional to that at the beginning of the experiment, and in animals with a relatively low glycogen content of the liver the

diminution of this substance may result

2. In rabbits with experimentally damaged livers the glycogen content of the liver is low. The addition of in-

sulin to administration of glucose in these animals causes a further decrease in hepatic glycogen

3. Insulin medication is not indicated in disease of the liver

The Pituitary and the Sugar Tolerance Curve*

By JOSEPH EIDELSBURG, M D, *New York City*

THE history of the relation of a disturbance in sugar metabolism to pituitary disease may be divided into two epochs, that prior to 1911, when rough, more or less scientific observations showed glycosuria with and without the administration of sugar in one group, and the inability, in another group, to produce glycosuria after the administration of sugar, and that epoch since 1911 when Goetsch, Cushing and Jacobson showed that sugar tolerance is increased in hypopituitarism, as determined by blood sugar determinations. From that date down to the present, numerous workers have verified that observation, and in various ways have applied it to the diagnosis of hypopituitarism, in the form of the so-called sugar tolerance curve. With the advent of insulin, and the demonstration of the opposed action between the posterior pituitary hormone and insulin, further evidence of this was shown (Burn).

The introduction of the sugar tolerance curve determination heralded a means of measuring this previously noted increase or decrease in sugar tolerance, but the lack of standardization of the procedure, and other affecting measures, has led to a series of results varying from one extreme to the other. On the one hand, John said "the increase in tolerance in hypopituitarism is characteristic, almost a straight line", and Hale-White and Payne wrote that "since most definite

cases of pituitary lesions tend to have an abnormal curve, the finding of a normal curve, may be considered to weigh against there being any abnormality of the pituitary functions". On the other hand, Engelbach, though having tried the application of a sugar tolerance curve determination, discontinued its use, and recently Glassberg wrote "I am unable to find any one curve which may be considered diagnostic of any of the conditions under consideration (endocrinopathies including hypopituitarism)", and further "I feel that the sugar tolerance curve as we have used it as a routine up to this time yields no information of diagnostic value in differentiation of normal and endocrinopathic conditions". Such extremely divergent conclusions demand scrutiny, study and explanation.

There are a great number of factors which influence the level of the blood sugar in an individual at any given time, and these factors may vary from day to day. The coexistence of a hidden lesion or lesions, with the apparent or suspected lesion, may greatly affect the sugar level, both before and after glucose ingestion—thus disturbances of the liver, pancreas, thyroid, changes in diet, disturbed gastrointestinal function, previous starvation or "dieting," excitement and medications. Thus "tolerance curves" repeated in a patient at an interval of even several days may not be identical. The amount of liquids and food taken prior to the test exert an in-

*Received for publication, Oct. 12, 1931

pain concurrent with venous puncture (especially when repeated failures are encountered), and numerous other factors, many non-apparent and not realized, all can modify the curve, in the same individual, and although John argues that the differences in the weight of the patient and the amount of glucose taken make but little difference in the curve, and the various observers use from 25 to 100 grams of glucose, some, on a fasting status, and others on *any* previous meal, with no definite time interval, we will attempt to show that the curves will vary greatly, with the variations in the amount of glucose, fasting, or food partaken.

Thus the same patient, under identical standardized conditions, (as described later), with a different amount of glucose, after a 48 hour interval showed the following differences

50 grams — 150 grams ----

Mgs. Sugar

Case 1

Case 2

Case 3

FIG 1

Compare the curves in a case of definite hypopituitarism in a boy (Lorain type of infantilism), given first 175 gram of glucose per kilogram of body weight, on Lorain later 150 grams of glucose, one week later.

52.5 gram glucose, i.e., 175 gram per 1 km body weight, body weight 3) km (Curve —). 150 gram glucose (Curve ----).

FIG 2

The first curve (—) is that of increased tolerance, while the second curve (----) is, to all intents and purposes, normal.

Note the difference below, in another case, figure 3, in the curve following a 48 hour fast (----), and the non-fasting curve with the same amount of glucose, 175 grams per kgm of body weight, (—), in the same patient, repeated after ten days.

FIG 3

Two hours before the curve (—) determination, a meal consisting of four slices of bread, dish of ice-cream,

one pastry and coffee, with two lumps sugar was given. After a study of this phase of the subject, Myers sums it up "it is well known that the tolerance for glucose is lower in the fasting condition than after glucose has been given, apparently as a result of its stimulus to the glycogen forming mechanism, due possibly to the liberation of insulin by the pancreas. At the end of three hours this initial stimulus still appears to be sufficient to enable the normal organism to readily handle the amount of glucose given without undue hyperglycemia." The importance of the so-called standard breakfast, as later described, is thus emphasized.

Further, the blood sugar curve varies with another factor—whether so-called capillary blood (obtained by finger puncture) or venous blood is used. Note the two curves below by Foster. Foster pointed out that the blood obtained by finger puncture is virtually arterial blood. "He has found that although the sugar concentration of venous and finger (also arterial) blood is the same in the fasting state, after the ingestion of glucose there is a more rapid and greater rise in the finger blood than in venous blood." To quote Myers further, who sums up the work of Foster in this regard "the logical explanation for this would appear to be found in glycogen formation in the muscle tissue, since the muscle stands between the arterial and venous blood. It is also apparent that when this glycogen synthesis has once been started it carries the sugar of the blood below the initial level as a result of overactivity of the glycogen forming mechanism."

Glucose curves—simultaneous ven-

ous and finger blood (Foster) Venous blood (—) Finger blood (----). Amount of glucose, 100 gm

FIG 4

In 1925 we showed that repeated injections of milk produced an increase in the sugar tolerance. Wood-yatt claims that some drugs such as phosphorus and arsenic may cause glycosuria by causing an increased glycogenolysis.

Therefore, to perform the test properly, and to properly evaluate the curve produced, the effect of the administration of various diets, drugs, injections, treatments, etc., must be kept in mind. It is then apparent that discrepancies in the curves repeated in the same individuals, with the same diagnosis, can be expected, depending on

- (1) Type of blood used for the sugar determinations.
- (2) Time of day the test is performed.
- (3) Time of the previous meal.
- (4) Nature and amount of the previous meal.
- (5) Degree of pain, anxiety, excitement and mental status of patient.
- (6) Dieting and treatment of patient for the days and weeks leading up to the test.

- (7) Amount of the fluid taken with or before the glucose.
- (8) Amount of glucose taken and its dilution.
- (9) Presence or absence of other co-existing pathology or lesions besides the suspected condition.
- (10) Individual peculiarities in rate of absorption, glycogenesis, rate of hormone manufacture, etc

For these reasons we have followed the method of Kilian, as standardized in the laboratories of the New York Post Graduate Medical School and Hospital Without any change in diet and habits, and prior to any medication (especially thyroid, thyroxin, insulin, antuitrin, pituitrin, foreign proteins parenterally, etc) the patient reports for his curve determination two hours after his breakfast which consisted of two slices of bread, one egg, and a cup of tea or coffee He is first given a drink of water, the amount equal to that which will be used to make the glucose a 50 per cent solution, and he empties his bladder One hour later, he voids again, and a specimen of venous blood is taken He then immediately takes the glucose, 175 grams per kilogram of body weight in 50 per cent solution Specimens of blood (and urine) are taken hourly for two, three and four hours It is true that by taking only the hourly specimens the highest point may be overlooked, but for practical purposes it suffices

Curves regarded as examples of normal tolerance

FIG. 5

From studying numerous such curves regarded as normal, we have reached the rough rule that the level at the first hour is approximately from 40 per cent to (60) per cent above the 0 hour with a tendency to return to about the 0 hour level at the end of the second hour.

We will confine ourselves at this time to more or less positive cases of hypopituitarism, without other complicating conditions, where the stigmata and clinical findings were well marked It has been our clinical conception from some years of observation that hypopituitarism does occur without obesity (as shown in the laboratory on animals by Smith), and can also occur without much change in the sugar curve. However it is our impression that the sugar curve deviation from the normal in uncomplicated hypopituitarism is a rough measure of the degree of hypofunction

Below are some illustrative data in a number of marked cases of hypopituitarism .

AGE	SEX	SELLA TURCICA	0 HR BL. SUGAR	1 HR BL. SUGAR	2 HR BL. SUGAR
14	M	50% undersize			
20	F	Congenitally small, clinoid processes almost completely bridged	82	90	87
18	F	50% undersize, with suprasellar shadow suggesting tumor	78	80	76
30	M	Large sella turcica, marked erosions	80 92	76 95	75 90

The curves in these cases approximate the flat curve, plateau or straight line described by John and others. Below are some illustrative data in a number of suspected or mild cases of hypopituitarism. We have seen a great number of such but have picked only a few to make this point clear.

AGE	SEX	SELLA TURCICA
25	F	1/3 undersize
30	F	Congenitally small
27	M	Negative
26	M	Congenitally small

It will be noted that here we had an elevation after glucose administration varying from 25 per cent to 37 per cent, as compared to the 40 per cent to 60 per cent rise in the normals.

The opposite syndrome—hyperfunction—may therefore give a decreased sugar tolerance, with the corresponding curve, such probably occurring in the so-called acromegalias with diabetes. These, because of treatment, x-ray or surgery, or because of a “natural burning out process” may gradually obtain an increase in their sugar tolerance, and as the original process regresses, or because of x-ray or surgery, may finally develop, as an end picture, the “flat curve” shown above, indicating, perhaps as an end picture, hypofunction.

The following case demonstrates this point. A lady, aged forty-five years gave a history of headaches of ten years duration, gradually increasing in frequency and severity, and lately noticed that her features were becoming heavier and her hands and feet larger. At this time the visual field determination showed a marked temporal constriction, and x-ray of the skull revealed a large sella turcica. Soon she began to have itching, thirst, polyuria and lost 20 pounds. Her sugar curve at this time was as follows—

0 HR	1ST HR.	2ND HR
162	305	294

She received intensive and continued x-ray therapy. Insulin and diet seemed to be of little value, and were soon discontinued. One year later her sugar curve was as follows—

0 HR	1ST HR	2ND HR
93	121	107

Clinically she has gained about 30 pounds,

0 Hr	1 Hr	2 Hr.
92	115	101
102	130	110
85	116	91
96	114	93

her headaches have practically ceased, her visual fields are markedly improved, and she has become somewhat obese, lethargic and slow. With the advent of a clinical syndrome, suggesting pituitary deficiency, the sugar tolerance has swung from the extreme suggesting the diabetic curve to the other extreme, the flat curve of hypopituitarism. The reader is referred to the writings of Colwell, Allen, Lesser, and others for such similar experiences, data and impressions.

In cases of hypopituitarism (non-tumor cases with small sella turcicas, obesity, etc.), having observed a number over a period of years (fifteen such cases having been followed about eight years), we could see the changes in the sugar tolerance curve, paralleling the improvement. Below are examples of this.

	0 HR	1ST HR	2ND HR
Case 1 (1923)	94	98	90
(1926)	87	110	92
(1930)	80	121	94
Case 2 (1925)	82	87	85
(1928)	90	111	90
(1930)	88	117	85

Gardner, Hill, Jones and Smith observed, too, that “with improvement the sugar tolerance curve approaches the normal.”

CONCLUSIONS

From the data, observations, and literature we find the following conclusions justified:

1 Certain pituitary hormones have an action on sugar tolerance, in some respects, diametrically opposed to the action of insulin.

2 The administration of glucose to an individual will produce a curve, if the blood sugar levels following this administration are plotted

3. The random administration of glucose—fixed amount of glucose for all patients regardless of size, fasting state, etc.—produces so variable a curve that its value in diagnosis under these conditions is nil

4 Capillary blood curves are not

identical with venous blood curves and should be discarded for curve determinations.

5 To be properly performed the method described should be followed, or some better method not yet devised

6 When thus carried out, other things being excluded, e.g., medications, diseases, etc., deficiency is frequently characterized by an increased tolerance, the degree of tolerance increase being a rough measure of the degree of deficiency

7. Pituitary hyperfunction is often associated with a decreased sugar tolerance resembling diabetes mellitus, but amenable in some cases to improvement, as the hyperfunction is controlled.

Clinical Interpretation of Jaundice Based on Physiologic Principles*†

By I W HELD, M D, F A C P., and MILTON KRAMER, M D,
New York City

THE tremendous value in diagnosis of bed-side approach, based on a large clinical experience is known to all. In many disease states, this suffices, and memory of characteristic symptoms, physical findings and laboratory data makes accurate diagnosis possible. The problem is not so simple in diseases associated with jaundice, a leading symptom that all may recognize easily, but which is due to so many conditions, intra- and extra-hepatic, that extreme difficulty often arises in interpretation. Here, experience alone, plus the most exact functional tests known, fails to lead to exact diagnosis in a vast number of cases. Notwithstanding painstaking reasoning and analysis, one must often admit doubt at the bedside, and defeat in the operating room or at the autopsy table. The difficulties presented prompt an attempt to create further clinical order, building upon a foundation of underlying physiologic and pathologic principles.

Jaundice is a leading objective symptom, a staining of the plasma and of the tissues, consequent upon increase in the bilirubin content, at the site of

discoloration, local or general. The tissues of the body, however, do not stain equally, some actually remaining free of pigment, no matter what the intensity of general coloration. Most highly colored are the blood vessels and heart valves, the skin, mucous and serous membranes, kidneys, lungs, spleen and liver. Cartilage, the cornea, and the cerebrospinal system (brain and spinal cord) retain their normal appearance. (A single exception here is the staining of the infundibulum cerebri in some cases of icterus neonatorum gravis.) It is also interesting to note that pure secretions, exemplified by the salivary and gastric juices, and the cerebrospinal fluid, are free of bilirubin. Excretions, as urine and perspiration are however, deeply stained.

Numerous attempts have been made to explain this inequality of tissue staining. The facts certainly oppose acceptance of the "imbibition" theory, with its claim for general tissue absorption of the bile pigments from the circulating fluids. If this mechanism was operative, one should expect an equal staining throughout. Rose and his co-workers have attempted to answer this question. His experimental work indicates the resistance of elastin to the associated staining of elastic tissue, as a factor in the

*Beth Israel Hospital, New York City

†Received for publication October 18 1931

chemical substance, attracting bilirubin. Those tissues rich in elastin stain deeply, those without elastin are free of pigment. Adipose tissue containing no elastic tissue appears intensely colored, only because of the small amount of pigment needed to contrast with the pure white of the fat. This color, too, can be washed off easily, which is not true of the other tissues. Elastin, *in vitro*, added to non-stainable tissues appeared to alter the response to the pigment. This chemical affinity conception also fails of complete satisfaction. It seems likely to us that the staining of a specific tissue is related also to the function of that particular tissue as regards bilirubin pigment — formative and excretory. It is most concentrated at sites of its formation in the reticulo-endothelial system (*vide* below), principally spleen, liver and bone-marrow, and also marked in organs of its normal and abnormal excretion — kidney, skin and intestines.

Here, one must pause momentarily to inspect the evidence concerning the nature, formation and excretion of bilirubin and its associated pigments.

Virchow² found crystals in extravasated blood, strongly resembling bilirubin. Knowing that they came from the hemoglobin of the red cell, though unable to furnish chemical proof of their identity, he named the substance hematoidin. The proof that this substance was bilirubin subsequently was furnished by Jaffé, Fischer, and Bumstead and Rich. The possibility has been suggested that bilirubin also may be formed from pigments other than blood hemoglobin. Myohemoglobin may contribute very slightly (Whipple, Hooper and Robschey-Robbins). The

importance of chlorophyll,³ and its associated pigment is denied (Bollman, Shepard and Mann). The only justifiable conclusion seems to involve blood hemoglobin as practically the sole source of supply for bilirubin formation.

Prior to Virchow, the conception prevailed that the production of bilirubin occurred exclusively in the epithelial cells of the liver. The great pathologist's finding was the first bit of evidence indicating the possibility of extra-hepatic formation. However, it did not attract its deserved attention for many years. The work of Minkowski and Naunyn⁴ (1886) also appeared to corroborate the longstanding belief. Their inability to produce jaundice in hepatectomized geese with hemolytic agents, as arsenureted hydrogen, led them to the dictum "without liver, no jaundice". Several years later (1889) Lowitt,⁴ producing hemolysis in the blood of frogs, found red cell debris, hemoglobin, bile pigment and an iron residue, in the Kupffer cells of the liver. He indicated that bile pigment could be formed outside the liver epithelial cell, but did not deny the latter's activity in this regard. In 1912, McNee,⁵ in the laboratory of Aschoff, repeated the experiments of Minkowski and Naunyn with identical results, but now, with a new interpretation. He ascribed the absence of jaundice to the absence of the Kupffer stellate cells, so large a portion of the reticulo-endothelial system in geese. The conception of this system had been formulated recently by the Aschoff school and McNee was first to attract attention to it in connection with bilirubin formation. The other

members of the reticulo-endothelial system are the cells lining the sinuses of the spleen, the endothelium of the lymph and blood vessels, the capillaries of the bone-marrow, the serosae, the endothelium of the suprarenals, omentum, lungs, hypophysis and the macrophages of the blood

Credit goes to Whipple and Hooper⁶ for stimulating the important researches which yielded the conclusive evidence. Their deductions, however, derived from producing jaundice in animals whose livers supposedly were excluded from the circulation, were challenged. Rich,⁷ Makino⁸ and others denied that the liver had been excluded completely enough. Mann⁹ and his co-workers, in their series of ingenious experiments, then successfully dehepatized dogs and were able to produce an icteric state with hemolytic substances. Immediate universal confirmation followed. Rich succeeded in producing jaundice following complete abdominal evisceration. The contrary findings of Rosenthal, Melchior and Licht,¹⁰ of the Minkowski school, who failed to produce jaundice in hepatectomized dogs, after injecting such substances as toluylenediamine, were largely vitiated by such work as that of Joannovics and Pick.¹¹ The latter's experiments indicated that the substances used were toxic to the liver cell, and thus could not produce icterus in the absence of the liver. A mechanism therefore appeared to exist, outside the liver, which could assume the function of bilirubin formation.

Much evidence points toward the cells of the reticulo-endothelial system as active in this extra-hepatic formation of bilirubin. Kodama,¹² in experi-

mental icterus, showed bile pigment in the Kupffer stellate cells before it could be found in the epithelial cells of the liver, and before it reached the serum. In mechanical icterus, the Kupffer cells contained much more of the pigment. Haldemann¹³ demonstrated marked deposition of pigment in the reticulo-endothelial cells of the bonemarrow, after injecting laked blood intravenously. Several groups (Mann,⁹ Ernst and Szappanyos,¹⁴ Komari and Iwao¹⁵) demonstrated increased formation of bilirubin in the spleen and bone-marrow after injecting hemoglobin into the blood flowing to these sites, and in the perfused spleen. Lepehne,¹⁶ and Eppinger¹⁷ believed their attempts at blocking the reticulo-endothelial system with substances such as collargol resulted in the diminished activity in this process of bile pigment formation. Rich⁷ in tissue culture studies, noted that only mesodermal cells were able to transform hemoglobin into bilirubin, and this intracellularly, possibly with the aid of an hydrolytic ferment.

Evidence certainly indicates that the cells of the reticulo-endothelial system are able to manufacture bile pigment under the abnormal conditions of the various experiments performed. Whether this is the only method adopted by the body in health and what proportion of the work is performed by the various members are questions still to be answered. It is unlikely as Mann first indicated that the reticulo-endothelial elements of the spleen and bonemarrow are exclusively concerned in the extra-hepatic formation. These deductions are in accord with dehepated animals which develop

transferable to the intact animal, with its liver and Kupffer cells *in situ*. His more recent work indicates that in the absence of liver and spleen, the rate of production remains normal, presumably due to bonemarrow activity. Certainly, the ability of reticulo-endothelial cells everywhere to form bilirubin is attested by numerous clinical instances—regional icterus (Umber and Rosenberg), jaundice associated with pulmonary intarction, that following intra-peritoneal hemorrhage, etc. From analysis of the evidence presented, the reticulo-endothelial cells of the liver, spleen and bone-marrow appear to be the normal agents for bilirubin production, with the remainder of the system also capable of so functioning under more abnormal conditions.

The following facts, however, seem established with a high degree of assurance (1) That bilirubin is formed practically entirely from the hemoglobin of broken-down red blood cells; (2) that the cellular elements of the reticulo-endothelial system are probably active in this transformation; and (3) that the epithelial cells of the liver merely excrete the pigment into the biliary radicles which convey it to the gallbladder and intestines. It is evident, therefore, that alterations in the bilirubin content of the serum, and thus the tissues, may result from single or multiple derangements anywhere along this chain of bilirubin formation and excretion. Jaundice or the state of increased bilirubin concentration therefore may be due to (1) an increased destruction of red blood cells, and overactivity of the reticulo-endothelial system (2) disease of the hepatic epithelial cells, and consequent in-

complete or absolute failure of removal of bilirubin from the blood, and incomplete propulsion into the biliary radicles, and (3) blockage of the excretory channels after proper channation by the hepatic cell.

Rich has contended recently that jaundice rarely, if ever, results from simple overproduction of bilirubin. It is his belief that the reserve power of the normal liver is so great that the organ can care adequately for any excess of bilirubin and invariably prevent the establishment of an icteric state. Disturbance of liver cell function is claimed always to co-exist. He ascribes great importance to atrophic changes in the epithelial cells about the efferent vein of the liver lobule, found in various anemic and infectious diseases. Experimentally, similar lesions have been produced, under conditions pointing toward anoxemia as the responsible factor. Although this work is highly informing and leading, it is questioned whether the facts presented warrant the entire clinical conclusion. It would seem that Rich is ascribing too great an importance to pathology, usually minor. It is likely that in chronic cases of "hemolytic" icterus that have persisted for an extended period, the degree of liver dysfunction may proceed to clinical significance. The usual case, with hemolysis of red cells the crux of the clinical picture, does not appear to require such preceding damage. Although it is true that jaundice of any marked intensity practically always has an hepatic element, icteric states of milder degree, though with definite hyperbilirubinemia and tissue staining, appear to result independent of such affection. The

increased production of bilirubin on red cell destruction may be conceived as an actual compensatory mechanism, a pigment being formed from the liberated hemoglobin which is tolerated well by the tissues, and a colorless iron-containing compound being split off which can be stored and utilized again.

It is upon the foregoing facts that our modern classifications of icterus are based. McNee¹⁸ called the first group, "hemolytic", the second class, "hepatocellular" or "toxic" and the third "obstructive". Although it is true that all three terms do not possess identical connotations (hemolytic and obstructive, pathogenesis, and toxic, etiologic) this grouping is simple, satisfactory, and adequate for clinical usage.

Recently, Stuber¹⁹ suggested changes in nomenclature, attempting to add to the functional descriptiveness of the terms previously employed. He referred to the hemolytic as the "superfunction" group, since here mere overproduction of bilirubin leads to its increase in the serum and tissues. Whether "superfunction" better typifies this group than "hemolytic" is questionable. The implication of blood destruction certainly is better given by the latter term, though "superfunction" is of value in indicating the overactivity of the reticulo-endothelial system. Where there is no evidence of actual hemolysis, as after hemorrhages (intraperitoneal, pulmonary), blood dyscrasias and reticulo-endotheliosis, the latter term would seem more desirable. The "hepatocellular" group to Stuber is known as the "retention type of icterus," since even the normal quantity of bilirubin produced is partially retained, the malfunctioning epithelial cell being un-

able to excrete it completely. The obstructive class is called the "resorption" group. Here, no overproduction of bilirubin is found, the liver cell can propel completely the pigment brought to it, but somewhere along the course of the bile ducts, obstruction is met, and damming back of bile takes place. The continuity of the bile canaliculi is destroyed, bile reaches the perivascular spaces and is resorbed into the blood capillaries.

Rich used similar terms in his suggested classification, though with somewhat different application. "Retention" was used for cases with indirect Van den Bergh reaction and acholuria, though with increase of urobilin in urine and feces. This group includes the various forms of "hemolytic" icterus and jaundice resulting from mild interference with functions of the epithelial cells of the liver—as by anoxemia. "Regurgitation" was applied to those cases with direct Van den Bergh reactions, bile in the urine, and little or no urobilin in the stools. This class contains the forms associated with necrosis of liver cells. This classification does not appear to attach sufficient importance to clinical symptoms, nor does it adequately segregate cases on the basis of their underlying causes. Thus jaundice due to acute yellow atrophy is so essentially different clinically from that following a common duct obstruction by calculus that regrouping is undesirable. The basis of division, i.e., using the Van den Bergh reaction is also undesirable since similar findings may exist in either group at some stage of the disease process.

It is important to appreciate that the classifications in use are not based

and with sharp or absolute boundaries. This follows because the diseases causing jaundice are not static; they are dynamic and may regress, or, what concerns us more may show progress. A case belonging to one group becomes modified, as a result of active etiologic factors and complicating pathological changes, and may actually deceive so that cause and effect are not distinguishable. To exemplify the progression of a disease process, with its final possession of the characteristic qualities of two or more groups, one may utilize a case of congenital hemolytic icterus. Here, the primary defect lies in the red blood cell, with its increased fragility leading to increased destruction, and hence, over-production of bilirubin. The case clearly belongs to the hemolytic or superfunction group. With the excretion of a concentrated bile, the scene is set for the formation of bile thrombi or actual calculi of bilirubin or mixed type. These form and may cause variable grades of obstruction with its attendant symptoms and findings. Now, both the formation and excretion of bilirubin are disturbed. Furthermore, Rich²¹ has pointed out that in the later stages of the disease, actual damage to the liver cell follows upon the long standing anemia, and its associated lowgrade anoxemia. Thus, the hepatocellular element is added with its disturbance in transferring bilirubin from the vascular to the biliary radicles. So, we have traced, in one disease state, progressive disturbance along the entire course of bilirubin production and excretion. Of paramount importance, however, is the understanding that the primary defect originated in the red

blood cell and its ease of destruction by the cell of the reticulo-endothelial system. It is on this basis that this condition is classified as "hemolytic" icterus, and with a yardstick of these standards other icteric states are sorted.

The nature and implications of the Van den Bergh reaction now concern us, to aid its better utilization in diagnosis. This test, dependent upon the response of serum or plasma to the diazo reagent, yields differences of diagnostic import. A direct reaction which follows promptly upon the admixture of the serum and reagent is obtained with bile and the blood in icteric states associated with biliary obstruction or liver cell damage. The indirect reaction which requires the addition of alcohol is found in hemolytic types of icterus. The biphasic reaction is intermediary. The question was raised whether the different reactions were related to an altered composition of the bilirubin after passage through the liver cell. Several physical and chemical differences suggested that this might be so, namely, that direct bilirubin is oxidized more readily (Van den Bergh, Andrews); that it is more easily absorbed by the protein precipitate on alcohol precipitation (Van den Bergh), that it does not pass into solution with chloroform (Grunenberg), that it is dialyzable through a collodion membrane (Hoover and Blankenhorn), which fact is probably related to the presence of bile in the urine in cases of obstructive and hepatocellular icterus, and its absence in hemolytic icterus. Recent work indicates, however, that the "indirect bilirubin" may exist in the blood in combination with other substances Feigl

and Querner suggest a lipoid linkage, Adler and Strauss, a protein combination. Thannhauser and Andersen claim that the addition of bile salts and cholesterol to an indirect bilirubin serum changes the reaction to direct, Stuber makes similar claims for uric acid. Barron's²² informing work is of importance. He added to normal blood serum increasing amounts of sodium bilirubinate, giving direct Van den Bergh reactions. Up to 12 mgm per cent, an indirect reaction was obtained, at 16 mgm per cent, a biphasic reaction, above this amount, a direct reaction. He concludes that "some constituent of the serum has a tendency to absorb bilirubin and prevents the immediate coupling with diazonium salts". A direct reaction would be obtained, therefore, when the amount of bilirubin present in the blood exceeds the absorbing ability of the important substances (probably serum globulin—Adler and Strauss, Barron), or substances are present in the blood (bile acids, cholesterol, uric acid) in large amounts, which by their stronger absorbability, prevent the absorption of bilirubin. The latter is then able to react immediately with the diazo reagent.

An understanding of the metabolism of urobilin also is necessary for proper analysis of its alterations in icteric states. Urobilin is the reduction product of the action of bacteria on bilirubin in the intestine (von Muller, McMaster and Elman²³). Some is reabsorbed from the intestine and returned to the liver for future use in pigment formation, some reaches the general circulation and is excreted by the kidneys, traces being found normally

in the urine. In the urine, urobilinogen is rapidly oxidized to urobilin. The threshold of the liver for urobilin is limited, and in the presence of liver cell disturbance, even the normal quantity cannot be cared for, more passes into the blood, and thus more is excreted in the urine. An increased urinary excretion also can be effected by an increased destruction of erythrocytes, with its increased production and excretion of bilirubin into the intestine, and therefore increased production of urobilinogen. Certain limitations of the diagnostic value must be noted, namely the increase in most acute infections where there exists no reason to suspect liver damage, the diurnal variation, more being excreted in the afternoon than in the morning, the failure of the kidney of chronic glomerulo-nephritis to excrete it, even in the presence of liver disease. It is evident that an increase of urobilinogen or urobilin in the urine can be utilized diagnostically only in conjunction with other clinical symptoms. Absence of these pigments in icteric states is, however, much more significant, indicating failure of bile to reach the intestine.

In attempting to differentiate clinically the types of icterus, our understanding of the extra-hepatocellular formation of bilirubin stands us in good stead. Proper appreciation of the fact that icterus may exist independent of significant liver cell dysfunction leads us to utilize clinical data more efficiently. We are able to segregate the entire group of hemolytic or superfunction icterus from those related to disturbance in the hepatic epithelial cells and bile passages. The normal excretion of urobilinogen is 1-2 mgm per day, and in the presence of liver disease, it is increased.

with icterus traceable to improper excretion of bilirubin, associated symptoms always are present pointing toward the liver as the seat of damage. In fact, not infrequently the patient directs attention to the liver area, in telling his story, covering it often with his hand. In catarrhal icterus, the vague digestive disturbances preceding the onset of jaundice, and the enlarged liver point the way. In obstruction to the ducts, the pain usually present, the tendency to acholic stools, etc., indicate the site of disturbance. The presence of itching favors this group. The Van den Bergh reaction is direct or biphasic, bile is present in the urine; urobilin may or may not be present depending on the amount of bile which reaches the intestines. *In the group of hemolytic icterus, where jaundice follows upon increased bilirubin production and a mere quantitative difficulty of liver cell excretion, the icterus exists as a leading objective symptom. Any concomitant subjective complaints point entirely away from the liver toward the cause of the hemolysis and its effects.* This is probably related to the before-mentioned fact that bilirubin, being the normal product of hemoglobin breakdown, is so well tolerated by the tissues and their cellular elements. In the congenital and acquired hemolytic icterus, the anemia and its consequences are outstanding, in the course of severe infections, it is merely an additional symptom, with chemical poisons leading to hemolysis, signs point toward this cause. The Van den Bergh reaction is indirect, bile is absent from the urine, urobilinuria is marked.

Is it possible further to analyze the functioning of the reticulo-endothelial

system and lead to additional aids in diagnosis? Normally, as indicated before, the destruction of red blood cells and formation of pigment take place in the Kupffer cells of the liver and endothelial cells of the spleen and bone-marrow. The excretion of bilirubin via the hepatic epithelial cells keeps pace, maintaining a constant level in the blood. Abnormally, in icteric states, it is conceivable that the process of pigment production may proceed along normal or abnormal channels. In hepato-cellular and obstructive icterus, the bilirubin is still the product of members of the reticulo-endothelial system, normally engaged in the exercise of this function of pigment formation. In true hemolytic icterus, a mere overactivity of the normal agents is at fault. We must recognize, in addition, however, a sub-group of cases of "super-function" or "hemolytic" icterus, in which members of the reticulo-endothelial system, everywhere in the body, not engaged normally in this activity of bilirubin formation also assume this function (endothelium of the peritoneum, the lung, the skin).

Clinical facts appear to substantiate this differential conception. In hepato-cellular and obstructive icterus, days intervene between the onset of activity of the causative factors and the occurrence of visible jaundice. For example, in catarrhal icterus, a period of prodromal symptoms of from four to five days to a week or more is found before the onset of jaundice. In calculus obstruction of the common bile duct, a period of forty-eight hours or more intervenes before icterus appears, with the exception of patients in whom

cholecystectomy has been performed previously. In congenital hemolytic icterus one cannot always define the true time interval, but even here, following the so-called "crisis", a period of several days elapses between the onset of the pain and the appearance of the deeper jaundice. A definite interval is noted following the activity of hemolytic substances — chemical or bacterial. In all these conditions, after removal of the local or general causes, the jaundice persists for a shorter, or usually, longer period, related probably to the greater degree of hyperbilirubinemia and also the greater ease of penetration and tissue staining of the protein-free bilirubin compound. Consequently, the need exists for a more prolonged period of recession.

On the other hand, in icteric states consequent upon bilirubin-forming activity of portions of the reticulo-endothelial system, not so engaged normally, differences are noted. If an extravasation of blood is slight, only regional icterus may follow, as in the skin following trauma. If moderate, as in an hemorrhagic effusion in the peritoneal cavity, or a moderate pulmonary infarction, moderate icterus is present. If a severe hemorrhage occurs within the body, universal icterus may occur. In icterus neonatorum, various gradations of this process may be seen, from small patches of regional icterus to complete jaundice (one of the main elements in this affection being the breakdown of red blood cells and actual formation of bilirubin by the endothelium of the skin). In all, the appearance of increased bilirubin (and associated pigments), locally and generally, is noted soon after the oc-

currence of the accident, usually only hours intervening. The discoloration in the skin appears soon after trauma (conjunctival hemorrhages alone remaining red until absorbed). Following massive hemorrhages into the peritoneal cavity as in ruptured ectopic gestations, or following large or multiple pulmonary infarctions, within six to twelve hours, the patient may be subicteric. The icterus of rapid appearance also has the faculty of rapid clearance, being gone very soon after removal of the causative factors.

It is essential, too, to note that disturbance in the bilirubin-excretory power of the liver cell may be of clinical importance in conditions where there exists neither visible jaundice nor latent jaundice, as evidenced by slight increase in the blood content of bilirubin. Interference with this excretory power of the liver is effected much more easily than with its numerous metabolic activities. In acute liver disease, all functions may be disturbed, often out of proportion to the degree of evident damage. In chronic disease, as cirrhosis, with its brunt of mesenchymal damage, the parenchymal cell slowly adapts itself to the acting forces and evidences no disturbed function unless taxed or overburdened. Proof of a relatively isolated dysfunction of the liver cell may then be demonstrated by taxing the individual with ingested or injected bilirubin. Bergman,²⁴ Ellbott,²⁵ and recently Harrop and Barron²⁶ considered "the bilirubin excretory power of the liver" the most delicate for testing the functional capacity of this organ. Results were found in patients and after se-

anemias, acute infections, postarsphenamine and catarrhal jaundice some months after clinical recovery— all indicative of mild interference with liver cell function

Although the bilirubin-excretory test does indicate some hepatic cell dysfunction, it must be appreciated that this sudden over-burdening of the liver cell with bilirubin by far over-exaggerates the method of occurrence of icterus within the body. The rôle played by the epithelial cell in the development of an "hemolytic" icteric state cannot be accurately inferred from the result of this test

It should be evident that the present conception of the physiologic principles underlying the formation of bilirubin and the causation of icterus has led us far from the old Minkowski-Naunyn dictum, "without liver, no jaundice". Extra-hepatic production of bilirubin makes possible the development of icteric states, by forces acting entirely or mainly outside the liver. The importance to be ascribed to associated changes in the liver cells, as found by Rich, is still not definite. Certainly, they may aid in the progress of jaundiced states, but whether they are present, or needed, at its inception is questionable. Clinically, as indicated, one is justified in separating entirely, those groups of icterus due to causes, active intra- or extra-hepatically. The

presence in the former of associated symptoms indicating liver disturbance and the absence in the latter of any subjective complaints pointing toward such dysfunction are facts of important diagnostic value.

Summary

1 Jaundice as a leading objective symptom, when due to over-production of bilirubin exists free of any complaints pointing toward liver dysfunction. Any associated symptoms or signs reflect the cause of the hemolysis and its effects.

2 When jaundice follows disturbed function of the hepatic epithelial cell or obstruction of biliary ducts, signs point toward the liver as the seat of damage

3 It is suggested that the group of "hemolytic" or "superfunction" icterus may be divided clinically, dependent on whether the abnormal quantity of bilirubin is the product of members of the reticulo-endothelial system normally engaged in this production (liver, spleen, bone-marrow) or abnormally so functioning (endothelium of skin, peritoneum, lung, etc.)

4 The bilirubin-excretory power of the liver cell may be utilized as an excellent test of liver function. Prolonged retention of injected bilirubin may be the only demonstrable evidence of a cellular dysfunction

Niemann-Pick's Disease^{*,†}

(Essential Lipoid Histiocytosis)

By ROBERT A. KNOX, M.D., F.A.C.P., and GEORGE W. RAMSEY,
M.D., F.A.C.P., Washington, Pa.

NIEMANN-PICK'S disease is a disease of infancy characterized clinically by an enlargement of the liver, spleen and lymph glands, associated with yellowish brown pigmentation of the skin and accompanied by an enlarged abdomen and more or less emaciation. Cranial and skeletal changes may be associated. It is a fatal condition, being characterized by progressive wasting. Death may be due to intercurrent affections. "It is a congenital, familial, constitutional, systemic disease which manifests itself as a disturbance of the lipoid metabolism and leads to a deposit of complex cellular substances in the cells of the reticulo-endothelial apparatus. Its etiology and pathogenesis are unknown. It does not yield itself to therapy."¹

In 1914, Niemann² described a peculiar form of splenohepatomegaly, occurring in an infant, which was fatal at eighteen months. Since that time, several cases have been reported. Extensive clinical and pathological studies have been made. These include cases reported by Knox, Wahl and Schmeisser,³ Siegmund-Koln,⁴ Bloom,⁵ Hen-

schon,⁶ Schiff,⁷ Hamburger,⁸ Corcan, Oberling and Dienst,⁹ Berman,¹⁰ Kramer,¹¹ Dienst and Hamperl,¹² Abt and Bloom,¹³ and Abrikossoff¹⁴.

Berman, in his report of a case in a girl of fifteen months, records the history of vomiting and abdominal distention since the second month of life. Enlargement of the liver and spleen was recognized at six months. Splenic puncture showed typical foamy cells and, at autopsy, the splenic pulp was found to be made up almost entirely of foamy cells, large, round, vacuolated and pale. He also reported a fractional determination of the blood lipoids.

Kramer's case was of a girl of fourteen months. The spleen had been enlarged since she was four months of age. Examination of the spleen, after a splenectomy, showed the tissues almost completely replaced by masses of large, pale cells of varying shapes with small nuclei.

Abrikossoff's case showed a moderate enlargement of the spleen and extensive involvement of the cranial and general skeletal structures. Thus, perhaps, justifies the assumption of a skeletal type of Niemann-Pick's disease after the manner of a skeletal type of Gaucher's disease.

Bloom and Kern¹⁵ concluded, from chemical analysis of the spleen, that, in

†From the Departments of Pediatrics and Pathology, Washington Hospital, Washington, Pa.

*Received for publication, September 2, 1931.

Niemann-Pick's disease, the stored material is chiefly phosphatids, probably lecithin and cholesterol. While in Gaucher's disease, the stored material is kersin.

In both cases, these pathological substances are deposited in the liver and spleen causing a marked enlargement of these organs.

The composite clinical picture presented by Abt and Bloom¹³ might, in many respects, be that of our case. The patient was mentally and physically retarded. The facies strongly suggested mongolianism. He could not stand, when he assumed a sitting posture, the head and shoulders drooped forward exhibiting a decided curve of weakness. There was little

interest manifested in what went on about him. Toys held no allurements. For the most part, he was content to lie quietly taking only a brief interest in the attendant, other children at play and even in his food. The temperature fluctuated, and his leukocytosis reached 22,400. The accompanying photographs portray the mongoloid appearance and the large ascitic abdomen. (Figures 1 and 2) After tapping, the decidedly enlarged liver and spleen were found to extend as low as the crests. (Figure 3)

Palpation and x-ray of the spine demonstrated an abnormality, probably a congenital defect. X-ray of the chest revealed alterations of the ribs, probably the bony involvement to which

Fig 1 Mongoloid appearance, ascites and edema of scro' a Pick's disease

Fig 2 Marked ascites associated with hepatosplenomegaly. Niemann-Pick's disease

Abrikossoff¹¹ called attention. An abnormal condition of the maxilla might be congenital or, more probably, further evidence of bony change indicating cranial involvement

CASE REPORT

Frank S., white, Austrian, twenty months old, was admitted to the Children's Department of the Washington Hospital, August 24, 1929, because of an enlarged abdomen

Five weeks prior to admission, he had an acute febrile disorder accompanied by an eruption which was probably measles. Two weeks before admission, the mother noticed his abdomen "seemed swollen" and had become progressively larger. At about the same time, she noticed that he was slightly jaundiced

Past History He was born December 13, 1927. Labor was easy, delivery spontaneous.

There were no birth injuries, cyanosis, hemorrhage or convulsions. He was the fourth child, full term breast fed until admitted to the hospital. He had had no previous illness except measles. He sat up at eight months, first tooth erupted at ten months. His first words were spoken at one year. At fifteen months, he was able to stand, using his crib as support. He was able to take a few steps at the age of seventeen months.

Family History. Father, mother and two sisters living and well. One brother died three days after birth, cause unknown. Neither of the two sisters shows any abnormality nor is there any history of illness comparable to the patient's disease in either the paternal or maternal families.

Physical Examination He was a rather poorly nourished and developed child of about twenty months, whose mental development seemed below that of the average in-

Fig 3 The same patient after withdrawal of the ascitic fluid

FIG 4 Cholesterolosis of reticulo-endothelial cells of liver sinusoids

Fig 5 More marked separation of liver cells by masses of foamy cells in the intercordal sinusoids

fant of this age. There was a slight yellowish pigmentation of the skin. The head was of the square type and seemed somewhat large in proportion to the rest of his body, circumference 50 cm. The anterior fontanel was almost closed. The sclera was distinctly visible above the cornea, the pupils were equal and reacted to light. Ears were negative. There was a marked mucopurulent discharge from each nostril, teeth were poorly developed and irregularly spaced, the alveolar process, on the left, was widened and partially covered with a white exudate. Tongue was thickly coated with a grayish brown exudate. There was mild inflammation of the mucous membrane of the pharynx. The anterior and posterior cervical glands were palpable. There was a questionable rigidity of the neck, the thorax seemed flattened antero-posteriorly and the costal margins flared outward and upward. The lungs were resonant, breathing was not labored but respirations were accompanied by distress. The apex beat of the heart was in the fourth intercostal space in the mid-clavicular line, impulse was barely felt, the sounds were clear and regular. The abdomen was markedly distended, showing many dilated veins. The abdominal wall was tense, there were signs of fluctuation, no masses could be felt. Genitalia were normal except for first degree hypospadias. The vertebral column showed a prominence in the lower lumbar region. It was widened and irregular. Bony prominences were felt laterally to the spinal processes which seemed to be more widely separated than normal. The extremities were swollen. The surface temperature of the hands and arms was below normal but less than that of the feet and legs which was distinctly cold. There was some swelling but no pitting on pressure. The reflexes were diminished or absent. By high rectal examination, a mass could just be felt.

The day following admission, respirations were more embarrassed and the abdomen was tapped and 3200 cc of straw colored fluid was removed, following which he was relieved. The abdomen was quite flaccid. The liver and spleen were both enlarged. The liver could be felt as low as the umbilicus in the midline and extended downward almost

to the crest of the right ilium. The spleen extended downward almost to a corresponding point on the left. Both masses were firm, hard and smooth with the exception of a nodule which seemed to be attached to the outer surface of the spleen.

Two weeks later, the abdomen seemed to be refilling. The head appeared larger, the circumference was 50.5 cm. The child took very little interest in his surroundings and was not eating well.

On September 18, the abdomen seemed to be increasing in size. The circumference of the head was 50.1 cm. Its maximum of 51.2 cm was reached one month after admission.

The spinal fluid was clear, globulin was increased, no increase in cells. Kahn test on the spinal fluid was negative. His blood picture, on admission, was Hemoglobin, 75 per cent, red blood cells, 4,530,000; white blood cells, 7,100, polymorphonuclears, 68 per cent, lymphocytes, 24 per cent; endothelial leukocytes, 4 per cent.

There was a progressive change from this picture to that of February, 1930, which was Hemoglobin, 65 per cent, red blood cells, 3,420,000, white blood cells, 22,400.

The urine showed at intervals a trace of albumen and, at times, rather numerous hyaline casts with some few white blood cells.

Aside from a mild bronchopneumonia in November, 1929, there was nothing unusual in his progress. He lost weight intermittently and failed rather steadily throughout the course of the disease which was terminated by death, February 22, 1930, almost six months after his admission.

Pathological Report The body is that of an emaciated child approximately two years old. The feet, legs, scrotum and penis are edematous. Congenital defects present are hypospadias and occult spina bifida in the lumbar region. There is marked distention of the abdomen and eversion of the costal margin. The head is large and square. The anterior fontanel is not completely closed. There is a deficient growth of hair on the head. The face has an aged appearance. Palpation gives one the impression of a mass below the right costal margin. There appear also to be masses in the lower abdomen.

The lungs are pale and grossly do not show

FIG 6 Groups of foam cells, lipid-containing reticulo-endothelial cells, in the spleen

Fig 7 Intertubular masses of mononuclear cells

suggestive changes. The lymphatic glands at the hilus are enlarged.

The heart has a pallid appearance but otherwise shows no pathological lesions.

The intestines are matted together and adherent to the parietal wall. The adhesions are dense and difficult to break up. Between the coils are found pockets of clear, yellowish colored fluid which is partly coagulated. The mesenteric and retroperitoneal lymph nodes are enlarged.

The liver is covered with a thick, grayish white membrane and is adherent both to the intestine and diaphragm. Separation of these adhesions is difficult. The organ is enlarged, especially the right lobe. On the under surface of the right lobe, there is a longitudinal fissure in which there is a grayish white nodule one centimeter in diameter. On section, the liver cuts with increased resistance and the cut surface bulges. The cut surface is of a pale, grayish color, with a mottling of irregular lighter areas.

The spleen is only moderately increased in size and shows a marked hyalo-capsulitis. On section, it cuts with increased resistance, the cut surface bulges and is of a dark red color with small irregular patches of a paler hue. The splenic corpuscles are indistinct.

The kidneys are of approximately normal size, pale, and the capsules strip readily. The cut surface is pale with a mottling of lighter areas. The medullary rays and pyramids are indistinct.

The spinal canal was opened at the point of the spina bifida and was found to contain a large quantity of clear yellowish fluid, partly coagulated. Gross lesions were not found in the cord.

The cortex of the ribs is thin and friable. The cancellous tissue is rarefied and paler than normal.

Microscopical Examination Sections from all the organs examined show extensive involvement with large, flat, irregular, round or polyhedral cells having small nuclei which are usually eccentrically located. The cell cytoplasm is finely granular, vacuolated and shows a delicate reticular structure. These cells apparently have their origin from the reticulum lining cells of the various organs.

Sections from the lungs show irregular groups of alveoli distended with these cells and compressing adjacent capillaries. The larger vessels are surrounded by wide mantles of the cells which have replaced the adventitia and the greater part of the media while the intima remains intact.

Sections from the liver show a diffuse involvement. In the periportal tissue the bile ducts and blood vessels are surrounded by these cells. In the parenchyma, the sinusoids are distended, the adjacent cells compressed and atrophic (figures 4 and 5). Wide areas show complete absence of liver cells, the new cells lying in a reticulum consisting of remnants of the walls of the sinusoids. In the nodular area, the cells are growing either diffusely or in small and large alveolar formation. Here also, the cells lie in a reticulum arising from the walls of the sinusoids.

Sections from the spleen (figure 6) show involvement of the capsule, pulp and splenic corpuscles. The cells are found about and within the corpuscles and in many cases only a trace of the lymphoid tissue remains. The splenic venules are involved in small and large irregular areas. The venules surrounding the involved parts are engorged with blood.

In the kidneys (figure 7) the cells are found growing either diffusely or in small and large alveolar arrangement surrounded by a delicate limiting membrane which is apparently derived from the kidney reticulum. In the involved areas these cells have largely replaced the kidney tubules. The glomerular tufts are also involved, practically all showing partial destruction of their normal structure and replacement with these new cells.

In the spinal cord, the cells are packed around the nerve elements which are degenerated and atrophic, many having disappeared completely.

The reticulum of the sympathetic ganglia also shows large groups of the characteristic foam cells (figure 8).

Sections from the ribs show the cortex thinned and immediately beneath it broad sheets of large pale cells surrounding a few fragments of bone trabeculae. Centrally, very little bone structure remains (figure 9).

FIG 8 Sympathetic ganglion with foam cells in the reticulum

FIG 9 Osteoporotic bone with marrow entirely replaced by cellular mass

The blood forming islands are invaded and greatly reduced in number. There is no evidence of osteoclastic activity by these cells but rather bone destruction seems to result from pressure atrophy.

Sections from a lymph node show the normal architecture destroyed. The new cells lie in a reticulum derived from the original structure. Only traces of lymphoid cells remain.

After mordanting the sections with bi-chromate of potassium, the fat in the cells takes a dark yellow stain with scarlet red and appears both as minute and medium sized globules.

A consideration of the extensive involvement of the various organs, the

evident relationship of the cells to the reticulo-endothelial system, the presence of fat in the cells and the absence of iron reaction as in Gaucher's disease, together with the age and early fatal outcome would seem sufficient evidence to establish this as a case of Niemann-Pick's disease.

Acknowledgment of our appreciation is hereby made to Dr F. I. Patterson, who contributed to the care of this child.

Photomicrographs accompanying this article were made possible through the courtesy of Dr E. T. Bell and his staff of the University of Minnesota.

Four Physiologic Defenses of the Upper Part of the Respiratory Tract: Ciliary Action, Exchange of Mucin, Regeneration and Adaptability*†

By ANDERSON HILDING, M D, *Rochester, Minnesota*

I SHALL give the results of some studies in connection with a tremendously interesting and but poorly understood structure, namely, the mucosa of the upper part of the respiratory tract. This work resulted from a study of the common cold.³ In connection with that, the textbooks and periodicals were thoroughly searched for an adequate discussion of the physiology and pathology of the nasal mucosa. Nothing satisfactory was found anywhere. Consequently, I began a special physiologic study.

In this presentation, four factors in the armamentarium of defense of the nasal mucosa will be considered. They are ciliary activity, exchange of mucin, regeneration, and what might be termed adaptability to environment. The regeneration meant is that repair which follows injury to the surface, as in the common cold.

The purpose of the presentation is to emphasize the great activity of this extremely delicate and much exposed

membrane. I think there is no structure in the body so delicate and so severely exposed to the environment as the nasal mucosa. One would expect an inert, resistant, leathery type of epithelium in such an exposed position. Instead there is a highly specialized, ciliated, fragile membrane. It exists, I believe, largely by virtue of its remarkably active systems of defense.

CILIARY ACTIVITY

Ciliary activity in general is well understood. Biologists and physiologists have developed the knowledge of this phenomenon in great detail. This knowledge, however, has not been applied to the nasal mucosa in an adequate fashion. Its importance has not been sufficiently stressed.

The motion of the cilia of the nasal mucosa of man is simple, whip-like and in two phases, there is an active phase in the direction of the flow of over-lying material and a phase of recovery. The rate is approximately 250 cycles a minute. The action is coordinated in a very remarkable manner. When viewed in profile the cilia are seen to beat in sequence in such a way that waves are formed and travel across the surface. When viewed from above, as seen in a field of granules, the cilia pass over the granules in a regular pattern. No two cilia are in phase.

*Read before the American College of Physicians, San Francisco, California, April 5, 1932, with motion picture demonstration.

†From the Section on Ophthalmology, The Mayo Clinic, Rochester, Minnesota. Work done in the Division of Experimental Surgery and Pathology, The Mayo Foundation.

wave are in exactly the same phase at any moment. When viewed from the front, on the other hand, rather small groups beat in unison. In military language, the ranks beat in unison and the files in sequence. In larger fields observed from above, I have received the impression at times that they are divided into strips that coordinate in such a way that adjacent strips beat more or less alternately. This would provide a hand-over-hand action that would greatly increase the effectiveness of the cilia in moving along the covering film of mucin. It is difficult to make certain that this hand-over-hand action is normal because it can be seen distinctly only when the ciliary beat is abnormally slow. The power of ciliary action is much greater than is ordinarily supposed. These tiny, hair-like processes, only five or six microns in length, move comparatively huge loads of overlying material that may be more than a hundred times as thick as the length of the cilia. The efficiency of ciliary action increases under loads until an optimal pressure has been exerted, and then decreases. The optimal pressure in the case of the epithelium from the pharynx of the frog is said to be about twelve grams per square centimeter.⁷ It is said to be less in the nose of man. In any case, the weight of the secretion in a mucin-filled maxillary sinus would not be sufficient to depress ciliary action on the floor, but would serve rather to stimulate it.

The question of ciliary control has not been settled. The action itself is automatic. Detached cells continue active, and even single detached cilia will beat if a bit of cytoplasm remains attached to them, as can be seen in mo-

tion pictures that I have made. In addition to the automatic action there must be a control of some type in order to produce that remarkable coordination. Whether it be nervous⁸ or on some other basis,⁹ is of no particular concern in this presentation.

EXCHANGE OF MUCIN

The speed of ciliary motion is bound up with the nature and the depth of the overlying film. Normally, the moist film that covers the nasal surfaces is a very thin, rather highly viscid, mucinous secretion. In a sense it is like one large, intact membrane or web that overlies all surfaces within the nose, sinuses, pharynx and esophagus. This web moves throughout its extent continuously. It has a certain tensile strength, and can sustain traction. This is a very important feature. There are some regions within the nose that normally are nonciliated. The web of mucin moves across these by means of traction exerted on it by the ciliated regions. From my studies it appears to me that this traction on the mucin is one of the most important factors in the successful accomplishment of normal drainage of the nose and sinuses. Gravity, on the other hand, plays only an incidental part, and is often a handicap rather than an aid.

The web of mucin moves backward within the nose over a fairly definite system of drainage, at widely varying rates of speed.⁶ Both rate of speed and direction are determined largely by the relation of the ciliated to the nonciliated areas. The regions in which the inspired air first makes impact are nonciliated.⁶ These vary somewhat in position and extent, according to indi-

vidual anatomic variations, but in general include the preturbinal region on the lateral wall, the anterior ends of the middle and inferior turbinates, and the anterior fourth of the septum. The presenting surfaces of spurs and ridges may likewise be nonciliated. The remaining surfaces, including the posterior two-thirds or three-fourths of the nose (exclusive of the olfactory region) are ciliated. In these studies the system of drainage was mapped by dotting drops of India ink over the surfaces and observing the direction and rate of flow as they moved back to the nasopharynx. The rate of flow over the ciliated areas was found to be comparatively great; namely, four to six millimeters a minute, whereas over the nonciliated areas, it was only a few millimeters an hour.

The direction of flow in the ciliated regions in general was backward, with a slight downward tendency. Over the

middle and inferior turbinates there was found a strong tendency for the flow to be diagonally downward, across the inferior border, into the corresponding meatus (figure 1). Apparently the reason for this is that the cilia are more active in the protected middle and inferior meatuses than in the more exposed, common meatus. In those regions, then, the web of mucin moves faster, and through traction drags the mucin from the areas of slower motion on the mesial side of the turbinates into the meatuses. It follows that the mucin does not necessarily flow exactly in the line of the direction of the beat of the cilia immediately underlying. Through traction it may slide diagonally across that line.

The direction of flow in the nonciliated regions appeared to be determined almost entirely by traction from the middle and inferior meatuses (figure

FIG. 1. The direction of the normal flow of mucus over the ciliated and nonciliated lateral wall of the nose. The flow along the indicated lines is rapid. The stippled area is nonciliated.

2) The motion was very slow. The lines followed by the ink converged at the anterior attachments of the turbinates and disappeared into the meatuses to emerge at the posterior ends. In a word, the nonciliated, inactive areas on the lateral wall drain very largely through the inferior and middle meatuses. It is to be remembered that this is the region in which dust, bacteria, cosmetics, and other foreign materials are most likely to lodge. Therefore, this foreign material drains back through the meatuses.

The drainage on the septum was found to be similar to that of the lateral wall. There was an inactive, nonciliated area anteriorly that drained very slowly through traction exerted on the web of overlying mucin. The rate was only a few millimeters an hour. Behind this area the surface was found to be very active (except on ridges and spurs) and ink drained at the rate of three to six millimeters a

minute. It took from only three to ten minutes for the ink to traverse the distance from the anterior third of the septum to the posterior margin.

In general, then, it may be said that the mucinous film covering the surfaces of the posterior two-thirds of the nose is replaced every ten or fifteen minutes. The film over the anterior third is renewed only about once each hour or two, and drains away through the meatuses. This may explain the fact that cultures made from deep in the nose are so often sterile.¹ Very few bacteria lodge deep in the nose, and those that do lodge there are swept away quickly. The regions where they lodge in large numbers drain very largely through the meatuses, where cultures are not usually taken.⁴

RAPID REGNERATION

Microscopic studies of warm, fresh secretion derived from patients with early colds, and of specimens removed

FIG 2 The direction of the normal flow of mucin as it is drawn by the cilia of adjacent areas over the nonciliated mucous membrane in the anterior portion of the nose. The lines converge at the anterior attachments of both turbinates, indicating that the mucin is drawn into the meatus.

for biopsy in the course of colds indicate clearly that there is extensive loss of the cells from the lining mucous membrane in the course of the common cold. In the first three days there are often great numbers of living ciliated and nonciliated epithelial cells floating free in the secretion (figure 3). During these days such cells greatly exceed the leukocytes in number. The nonciliated forms are the immature replacement cells normally found deep in the epithelium. Their presence indicates that the destruction goes deeply into the epithelium. This has been found to be the case in specimens removed for biopsy. Sometimes there is only a single layer of cells left in place

on the basement membrane.³ Yet it is rare that true ulceration occurs or that the underlying tissues are destroyed. It is inferred that the epithelial cells slough out in response to surface irritation and are replaced repeatedly with facility and great rapidity. The injury goes deep into the epithelium and causes extensive destruction, yet in a few days the epithelium is once more entirely normal.

ADAPTABILITY

The finding of active and inactive areas of drainage within the nose, and the determination that the mucous membrane of the active areas was ciliated and that of the latter nonciliated,

FIG. 3. Epithelial cells and leukocytes found in the secretion of a patient with a cold. Most of the cells are epithelial cells.

suggested study of histologic changes in the epithelium after the normal ventilation had been altered experimentally. The point to be determined was whether the various types of epithelium within the nose and sinuses are produced by variations in exposure to flow of air in the individual case, or whether the inference is that they are produced only by long ages of evolution. Two series of experiments were performed. The results indicated clearly that the nasal mucosa has a chameleon-like property of altering its form radically, according to circumstances.

In one series of experiments the right nostril of each of eight rabbits and of two dogs was closed surgically, causing the animals to breathe through one side of the nose only. The animals were killed after periods varying from

three weeks to six months, and sections from various parts of the nose were examined microscopically. There were marked changes on both the open and the closed sides in the rabbits. In the dogs there were marked changes on the open side only.

The histologic alterations on the septum on the side of the open nostril were in the nature of an extension backward of the area of squamous-like epithelium normally found just posterior to the vestibule. In those animals that lived longer, this type of epithelium extended well over half the length of the septum. The cilia were lost and the cells became stratified (figure 3). Going further backward, it was found that the epithelium became transitional and finally columnar. The mucous membrane of the elaborate turbinate became stratified and very much thick-

FIG 4 Section through the nasal septum of a dog four months after surgical closure of one nostril. The epithelium of the open side is uppermost. There is a marked change from the high columnar of the closed side to the squamous-like epithelium of the open side.

er than normal. In the meatuses the cuboidal epithelium became columnar, and short columnar epithelium became tall columnar. Within the sinuses there was practically no change. In a word the degree of change was proportional to the exposure to the impact of inspired air.

In the rabbits there was a very marked change on the closed side also. The distribution was similar to that of the changes on the open side, greatest on the anterior part of the septum, and least within the sinuses. It consisted in a very great increase in the numbers of goblet cells, that is, non-ciliated, mucin-filled cells. Over the anterior portion of the septum every cell, practically, became a goblet cell some months after closure of the nostril. Further back on the septum, ciliated cells also appeared. About half way back there were equal numbers of ciliated and goblet forms, and the further back the examination was carried the greater the number of ciliated cells and the fewer the number of goblet cells found. There was also a marked increase in number of goblet cells over the turbinates, the number became progressively less marked posteriorly. This increase in goblet cells was not noted within the sinuses.

In another series of experiments the frontal sinuses of a number of dogs were fully exposed to the outer air by removal of the roof and overlying skin. This sinus epithelium also changed markedly. It changed from cuboidal to columnar in the spots that were best protected and became stratified in the most exposed spots.

These experiments indicate several things. First, it seems certain that the

epithelium can alter its form radically in a comparatively short time, according to the demands made on it, and the various pictures of epithelium found do not represent different types of epithelium, but merely various forms of the same general respiratory epithelium. These experiments point to a probable explanation of the islands of squamous epithelium so commonly found in the trachea. Doubtless there are eddies in the streams of respired air that strike the tracheal wall with some force in those areas. The fact that there was no change in the sinus epithelium, either on the closed or on the open side in the series of cases in which one nostril had been closed, indicates that ventilation of the ostia of the sinuses may not be as essential as has been believed. The accidental finding of the tremendous increase in mucin-containing cells suggests the possibility that goblet cells represent only a phase in the life cycle of the ciliated columnar cell. Perhaps instead of two types of cells in this epithelium there is only one type.

SUMMARY

The epithelium of the upper part of the respiratory tract is not simply a static structure, with a feeble tendency to move overlying materials. It is dynamic. It is intensely active. The ciliary beat with extreme rapidity and moves tremendous loads of mucin and foreign material with speed, power, and efficiency. The ciliary motion is dependent on the overlying film of mucin that is so much like another living membrane. In the major portion of the nose this film of mucin is continuous

frequently. It may be said that there is a complete new lining over all the ciliated areas every ten or fifteen minutes. These portions are generally sterile. Even the nonciliated, inactive areas in the anterior fourth of the nose have an exchange of mucin every hour or two. When an irritant attacks from the surface, the mucosa sloughs its injured cells readily, before they are dead, and replaces them very quickly.

Prolific regeneration seems to be part of the physiologic process. Under certain conditions the percentage of goblet cells contained can be made to increase very greatly. When very much exposed to the force of flowing air and foreign particles, the epithelium of the membrane is altered in form from ciliated columnar to squamous-like. It ceases its tremendous activity, and becomes passively resistant and inert.

Paranasal Sinusitis

A Problem in General Medical Practice*†

By ARTHUR D. DUNN, M.D., F.A.C.P., and F. LOWELL DUNN, M.D.
Omaha, Nebraska

THE etiologic relationships of paranasal sinusitis** to systemic disease belong to the unsolved problems of clinical medicine. This is shown by the relatively increasing frequency with which patients suffering from conditions which may be referable to sinus disease find their way into the hands of consultants. The possibility of sinusitis as a causative factor must occur not infrequently to every physician who sees in chronic localized infection the solution of a considerable number of obscure diagnostic and therapeutic problems. Occasionally gratifying results have followed treatment advised on the basis of sinus etiology. However, failures have been so disappointingly frequent

that skepticism and prejudice have tended to so displace rational thinking in the minds of many physicians, that some have come, as a matter of principle, to denounce almost all forms of sinus surgery. This unsettled state of affairs would seem to arise from — (1) lack of adequate routine study and evaluation of the sinuses in common clinical conditions, (2) lack of and slow diffusion of knowledge of sinus physiology and pathology, (3) lack of recognition by internists and rhinologists that many of their problems are mutual and require enlightened cooperation for their solution, (4) technical misconceptions and inadequacies.

The following are some of the symptom complexes we have seen associated with sinus disease in which it seemed reasonably certain to us that the sinusitis was a determining or aggravating factor: (1) Headaches acute and recurrent "nasal ganglion syndrome", (2) "Eye strain", (3) Icteric streaks simulating typhoid endocarditis low grade sepsis, (4) Toxic conditions — athrepsia, marasmus, debility, certain anemias, (5) Bronchitis, acute and chronic (occasionally associated with tuberculosis), bronchiectasis, emphysema, (6) Allergic rhinitis and hay fever, (7) "Fog" or "clouding"

*Presented at the San Francisco Meeting of the American College of Physicians, San Francisco, April 5, 1932.

†From the Department of Clinical Research, University of Nebraska College of Medicine.

**The subject matter has to do almost entirely with chronic hyperplastic sinusitis. While acute empyema of one or more sinuses is not uncommon empyema is quite often a suppurative phase of chronic sinusitis. Acute suppurative conditions must be handled conservatively. Time and observation will often decide whether a simple acute process or an acute suppurative phase of chronic hyperplastic disease is present.

asthema, neurasthenia, mental disorders, (8) Focal complexes such as arthritis, myalgia, nephritis, myocarditis, neuritis, herpes, "colitis", etc; (9) Tic convulsif, spasmodic torticollis, "athetoid conditions".

Obviously sinus factors will be much more frequently diagnosed if they are suspected. Certain "leads" will be found useful in directing attention to the sinuses as a possible source of trouble, such as (1) Any of the sinusitis complexes mentioned above, (2) Facies "dull, puffy, weary eyes", "swollen nose and face", mouth breathing, nasal twang; (3) History of onset with a remote or recent "flu", with repeated colds, or following dental extractions, of undue sweating and chilliness, (4) History of chronic catarrh with nasal discharge or pharyngeal dripping; (5) Lateral pharyngeal lymphangitis, pharyngitis with visible mucoid, muco-purulent or purulent secretions in the nasopharynx; (6) Cervical adenopathy, especially of posterior chains.

The diagnosis of a sinus factor in systemic disorders should be made only after a complete clinical survey. The making of a diagnosis of a responsible sinusitis without the help of the rhinologist should be encouraged. It promotes independent thinking, prevents servile acceptance of "specialized" opinion, and helps to place the therapeutic decision on the shoulders of the general physician, where it belongs. It makes available advice based on the study of the patient as a whole. The fact that a chronic sinusitis is present is merely of interest, whether he who has the sinusitis suffers general ill health as a consequence of his sinusitis is another matter.

Roentgenology is by far our best objective method. The roentgenologist who takes pride in the accuracy of his positions, in the correctness of his exposures, and in the quality of his photographic work is a valuable ally. Opinions, even of highly trained and experienced roentgenologists, who are inclined to substitute interpretative skill and experience for poor films should be accepted with reservations. A word should be said for the use of a "scout" plate in the Waters position, even when there is little reason to suspect trouble. A normal film in the Waters position will go far toward ruling out a chronic sinusitis. If the clinical evidence still points to the sinuses a thorough rhinological examination with films in additional positions, with or without lipiodol, may be necessary. The general physician should acquire experience in film reading that his patient be not subjected to the liabilities of highly specialized interpretations. Finally, the platitude must not be forgotten that roentgenography reveals merely disturbances in densities and contour at a given time, and tells us little of the nature or behaviour of the pathological conditions present. The clinical records are often of more value than the ray findings. Occasionally repeated roentgenological studies are necessary to reach a decision. Such examinations are especially useful when allergic swellings of the sinus mucosae are in question.

Study and observation of the patient over considerable periods of time may be required. It may be necessary to follow his trouble through several recurring cycles in order to ascertain whether there is a hook-up between the patient's general and local symptoma-

tology The failure of rest, appropriate hygienic measures, or a change of climate to bring the patient back to normal and keep him there, seasonal variations, and exacerbations in the patient's ill feeling with increase in upper respiratory symptoms are all significant The disease history of chronic sinusitis has not yet been written Its relationships to allergy, diet deficiencies, endocrine disorders, climatic factors, superheated moisture-poor air, repeated colds, and to fatigue and exposure are not well understood Obviously the problem is large, the solution difficult, and it calls for continued and comprehensive studies

There seems to be a lag in our knowledge of sinus pathology There is little on the subject in the text books The three volume English version of Kaufmann devotes less than a page to inflammatory disease of the sinuses The sinuses are rarely investigated at autopsy and then only at the request of the clinician Yet Harke¹ found 138 instances of gross inflammation of the paranasal sinuses in 395 autopsies It would be interesting to see what change a routine postmortem exposure of the paranasal sinuses might work in our medical thinking on such subjects as lung abscess, meningitis, asthma, bronchiectasis, endocarditis, nephritis, and obscure septic and toxic conditions In autopsies on deaths from asthma in which symptomatology referable to the upper respiratory tract is the rule, the sinuses have received scant attention In the study of three cases of bronchial asthma with detailed postmortem analysis Kountz and Alexander² do not mention the sinuses Huber and Koessler,³ in their well known analysis

of the pathology of fifteen cases from the literature and six personal cases in which they have confined themselves largely to the microscopic examination of the lungs, mention the paranasal sinuses only once—"Catarrhal rhinitis with retained mucus in the left maxillary sinus" in a case reported by Marchand⁴ In Wright's⁵ case, although the calvarium was removed, and although the clinical history pointed to a chronic sinusitis, there is no record of the paranasal sinuses having been examined at the autopsy

Some of our lack of autopsy knowledge of paranasal sinus disease may be attributed to the want of any convenient method of exposure The chisel is unsatisfactory and the sagittal head-splitting technique of Harke, although providing satisfactory exposures, gives most morticians a cold chill One of us (F L D) has devised a core drill fitted to a brace (figure 1) * The center drill is placed in the sella turcica and is directed in the midline and in the plane of the facial notches of the mandible (figure 2) The core (figure 3) brings out the sphenoids, the posterior ethmoids and part of the nasal cavities and turbinates, generally shears the mesial walls of the maxillaries and leaves the pharynx, tongue and tonsils exposed By making a sagittal section of the core one will have had a complete exposure of all of the paranasal sinuses save the frontals and remaining ethmoids which may be easily opened through the orbital and ethmoid plates with a chisel

Current conceptions of chronic sinusitis

*Arrangements have been made with the Messrs. A. M. Miller and Company, Chicago, Ill., to have this core drill

pathology are based largely on material removed at operation. The process is considered to be an inflammation with epithelial hyperplasia. Eggston⁶ gives the following histopathological classification: (1) hypertrophic and polypoid, (2) atrophic or fibrotic, (3) mixed types. A better classification is that of Runge⁷ who considers chronic inflammation of the sinuses as chronic catarrhal and chronic purulent, both hyperplastic. The latter he sub-divides

into (1) an edematous or hypertrophic type, (2) a granulomatous or papillomatous type, and (3) a fibrotic type. It would seem that the various types described are merely different reaction patterns in the same pathological process. The multiplicity of pictures observed are conditioned by varying tissue responses to irritants, by the number, character and duration of acute infectious insults and by varying degrees of swellings and unswellings.

FIG 1 Core drill Two inches in diameter as used for average and large adults

which may profoundly change the reaction patterns in relatively brief intervals of time. One may obtain sections from a single sinus which run all the histopathological patterns described by various authors as different "types" of hyperplastic disease (Figures 4, 5, 6, 7). One of the most striking variations is in the water content. Wherry⁸ sees in tissue hydration a condition necessary for bacteria to invade the emulsion colloids of the body. In the abnormal variations in the water content of the mucous membranes may lie the

tendency in certain individuals to repeated upper respiratory infections. In this connection it is interesting to note that most hay fever patients ultimately develop a chronic sinusitis. Massive hydration and dehydration of the sinus mucosa accounts for the startling variations observed in allergic individuals by Proetz⁹ and others. Hydration factors and the high variability of the tissue reactions seen bring up the question of whether a pathological classification made on the basis of reversibility might not be more useful. As clinicians we

FIG. 2. Midsagittal schematic section of head showing area of exposure and portion included in core. The core includes sphenoid, posterior ethmoid, the posterior nasopharynx, tonsil of Rosenmüller, posterior part of the soft palate, the tongue, pharynx, and back teeth are accessible.

are primarily interested in whether changes observed are fixed or relatively transient, whether changes revealed by roentgenograms with or without lipiodol or by endoscopy are reversible or irreversible, and what are the corresponding histopathological patterns. Such knowledge will ultimately determine the indications for conservative or radical methods of treatment.* In

*Correlation of results obtained by radical operation with the type of inflammatory reaction present in the tissues submitted has shown that favorable results are more likely the deeper the tissue infiltration, where the inflammatory reactions are superficial the process is quite likely to be a pansinusitis and belong to the allergic type. Fibrotic membranes are commonly associated with suppuration and are irreversible.

the problems of tissue hydration are involved the baffling interrelationships of asthma and upper respiratory infections. There is evidence that the answer to many of the bacterial asthmas will be found in chronic infections of the sinus mucosae.

It is unfortunate that we are forced to resort to pure morphological methods to identify bacteria in mucous membranes. Although rigorous precautions be taken to insure a sterile technique, deductions from cultures obtained from sinus membranes are open to the criticism of contamination. We have repeatedly found bodies in the deeper areas of tissues stained by the Gram method which in our opinion are diplococci (figure 8). Similar findings

FIG 3 Core sawed open by sagittal cut

have been reported by others* 10, 11, 12

If pathogenic bacteria reside in diseased sinus tissues and find conditions more suitable to their growth in the deeper layers, obviously only those operative methods which accomplish a removal of the entire membrane should

*Cultures made with aseptic precautions from the mucosa of an asthmatic showed an organism in pure culture similar to those demonstrated later in the tissues. The cutaneous reaction to this organism was very sharp. The patient became immediately free from asthma following exenteration of his maxillary sinuses. Three months later a cutaneous reaction to the vaccine could not be obtained.

be considered in testing the focal infection theory as it pertains to chronic sinusitis. In analyzing our material the percentage of desirable clinical results was greater in those cases in which the material removed formed "casts" of the sinuses suitable for photographic reproduction (figure 9). When the specimens were badly torn or in fragments (figure 10) the follow-up showed a higher percentage of therapeutic failures. In other words, results were roughly proportionate to the degree in which an *en masse* removal of the diseased sinus mucosa was approached.

Chronic hyperplastic sinusitis as a

FIG. 4. Case no. V. V. H. Low power of portion of maxillary sinus showing various pathological processes which may be present in the deeper layers. ed = edema and hydrops; fib = fibrotic deeper layers; bv = bloodvessels.

focus of infection has not been generally accepted. Some maintain that chronic (suppurative) sinusitis rarely if ever acts as a focus of infection,¹² others that it is not an uncommon source of systemic disease.¹¹ A partial explanation of such wide variance in opinion may well lie in the technic employed in treatment. Drainage of a sinus merely gives a sick membrane a better chance to get well by helping it to rid itself of its secretions. Drainage in no way eliminates the focus. Washing with antiseptic solutions should have about the same effect on a chronically infected mucous membrane as the same type of treatment might have

on chronically infected tonsils. Curettement of the mucosa should yield approximately the same results as curettement of tonsils, and it has been amply demonstrated that incompletely removed tonsils merely become greater liabilities from a focal infection standpoint. The validity of clinical experiments to determine the rôle of chronic sinusitis as a focus of infection hinges on a technic which will approach a bacterial excision of the focus. To strip intact diseased mucous membranes of varying degrees of friability from the walls of bony cavities of low accessibility requires the perfection of a surgical technic totally different from any hith-

FIG 5 Case no. V, V. H. Higher power showing the hydrops and epithelial proliferation together with the inflammatory infiltration.

erto known Bacteriological, immunological, and pathological studies with animal inoculations will be helpful, but unless unanticipated methods be developed the solution of the problem of sinus infection in systemic disease in the final analysis will come from a statistical treatment of large series of clinical experiments, *the validity of which rests on rigorous diagnostic studies and a surgical technic which accomplishes an en masse excision of infected tissue with minimum trauma and without post-operative hemorrhage*

Results obtained in divers conditions such as chronic bronchitis, bronchiectasis, asthma, chronic arthritis, fag, nephritis, myocarditis, chronic heart

muscle insufficiency, low grade toxic states, etc, in selected cases, have convinced us of the focal possibilities of sinus disease Exenteration has been advised in patients whose troubles have been of some standing, who have undergone long and various treatments, and whose sufferings have been such as to make them willing to submit to any treatment that offered even a remote chance of success We have never advised exenteration in troubles of short duration, or where there seemed any likelihood of improvement by less radical methods Care has been taken to eliminate dento-alveolar sources of chronic sinusitis Removal of affected teeth and diseased bone by

FIG. 6 Higher power of section 5

alveolectomy^{4, 15, 16} has been advised, letting the sinus mucosa alone if there seemed to be any reasonable chance of

*This operation, first devised by W. L. Shearer for cosmetic purposes, as developed and used by him is a highly satisfactory method for the removal of pathological conditions of the mouth. The mucoperiosteum is deflected from the alveolar processes and the teeth removed, all pathological tissues are exposed and removed "under the eye", the bony tissues are trimmed and smoothed, and the muco-periosteum trimmed and sutured. Healing is by primary intention. The "reactions" so common to other methods for the removal of teeth and mouth lesions are practically unknown. This method, when correctly applied, permits the removal of all lesions of the mouth at one sitting without fear of dangerous reaction. Twenty years

recovery from removal of the adjacent diseased tissue. Partial excision of the mucous membrane has been tried in a few instances with questionable results.

What we have said has been based largely on our experiences with chronic disease of the maxillary sinuses. The more nearly the condition has been confined to the maxillaries the better have been the results. The maxillaries are more accessible from both diagnostic and surgical standpoints. A larger mass of infected tissue can be com-

experience with this technique has convinced us that in proper hands it is the method of choice for removal of dento-alveolar foci of infection.

FIG 7 Fibrosis in deeper layers

pletely removed with less technical difficulty—a quantitative advantage. Satisfactory improvement occasionally follows maxillary exenteration in the face of involvement of the sphenoids and ethmoidal labyrinths—also a quantitative effect. We have made no studies of bone involvement described in connection with chronic sinusitis. Autopsy studies of this problem would seem pertinent.

The following brief abstracts from case records illustrate the results that may be obtained in favorable cases, and in which it seems reasonable to assume that the exenteration of diseased sinus mucosae has been a determining

factor in the patient's improvement or recovery. Failures have been present, especially in pansinusitis in patients in whom we have had reason to suspect that the exenteration has been incomplete, or when the systemic conditions seemed to have become fixed, when other variables have been present or the focal nature of the trouble questionable.

CASE REPORT

Case No 1 E S L, single, 19, entered the hospital March 25 1925, with a diagnosis of acute rheumatic fever and acute endocarditis. She gave a history of yearly recurrent attacks of acute rheumatic fever from the age of 5 until her tonsils were removed at 13. She was known to have a

FIG 8 Diplococci indicated by arrows. (G. W. C. C.)

FIG 9 Case no VII, M C En masse exenteration of both maxillary sinus membranes Coronal section The material has been removed in one piece and the membrane is complete except for the usual tearing along the medial wall near the ostium

FIG 10 Exenteration of left maxillary sinus membrane by usual method Such material makes any opinion as to the completeness of the operation hazardous and suggests at least considerable trauma

damaged heart but her health had been reasonably good from that time until three weeks prior to her admission, when she contracted a cold, which was followed by a low grade fever. There was a profuse nasal discharge and she ached all over. Her knees became red, swollen and very painful, and she grew short of breath.

The physical examination showed a pale, young woman, orthopneic with acute rheumatic manifestations. The heart action was rapid. The apex was in the fifth interspace, 9 cm from the median line. The heart was 12 cm broad at the fourth interspace. From the heart findings a diagnosis of lesions at both mitral and aortic valves and of acute fibrinous pericarditis was made (the friction rub disappeared in 72 hours).

The urine examination was negative. The blood count showed a hemoglobin of 80, red blood cells, 4,200,000, leucocytes, 12,700. The Wassermann test was negative.

A remittant fever continued uninterruptedly for three weeks and on account of the history, rhinological and roentgenographic findings an attack upon the sinuses was decided upon in spite of the desperate condition of the patient.

Exenteration of the infected ethmoids and intranasal drainage of the maxillaries and sphenoids on both sides were done. Pus was found in both maxillary sinuses. Five days after the operation the temperature reached and held the base line. Convalescence was uneventful.

Comment. From the history, findings and clinical course one would have been justified in assuming an acute rheumatic or subacute bacterial endocarditis affecting previously damaged valves. Because there was a history of onset with an acute upper respiratory infection and clouding of the maxillary sinuses we decided to consider the sinusitis as a source of infection with or without a complicating acute or subacute endocarditis. On drainage of the infected sinuses a condition presumably of a precarious out-

look, became relatively benign. Serious re-infection, if any, of the endocardium had not occurred. The sinusitis was responsible for the febrile course. We have seen several similar cases and have come to consider the diagnosis of acute infectious endocarditis, even in the presence of obvious heart findings, as hazardous without excluding acute or subacute paranasal sinusitis. In the case under consideration we thought the sinusitis was of the acute suppurative type and the changes probably reversible. The patient has had no illnesses since, and would be considered a perfect physical specimen were it not for the valvular heart lesions. A Waters plate at the present time, however, shows hyperplastic membranes which were best removed as a preventive measure.

Case No. II. D. P., a young, married woman, age 23, was brought to the hospital July 27, 1929, with asthma, which had completely incapacitated her for the past six months. There was a history of repeated respiratory infections "pneumonia" at 4, 17, and at 19 when she was sick six weeks. The first attack of asthma had occurred in August, 1926. She had changed climate three times, elimination diets and protein tests had failed to reveal any allergic factors. Both maxillary sinuses were radiopaque. A clinical survey revealed nothing of significance except the signs of a chronic bronchitis with emphysema and a leucocyte count of 10,300.

Middle turbinectomy and radical exenterations of the mucous membrane of both maxillary sinuses were done. Both sinuses were filled with polypoid thickening and were filled with pus. The mucous membrane was decidedly fibrotic in type with marked vascular change. The epithelium was normal but in places atrophic. A large share of the specimen was sent for bacteriological examination. No bacteria were cultured. Diplococci were present.

A report on Jan 30, 1932, states "I am in better health than since childhood I have had no bad attacks of asthma. Once in a while if I run or exercise too hard in the cold I will "stuff up" for about 10 or 15 minutes. At times when out in the cold or just before a storm my face hurts and I have pain between the eyes and in the cheeks" (probably ethmoid disease).

Comment This is a fairly well controlled case of severe intrinsic, incapacitating asthma, in which prompt and complete relief followed a radical exenteration of the diseased mucosae of both maxillaries. Asthma patients should be studied from the standpoint of sinus infection either as a causative or a complicating factor. Severe cases, obviously intrinsic, with hyperplastic sinusitis should be given the benefit of the experiment of a complete exenteration, especially if the disease seems to be confined largely to the maxillaries. After all, as Rackemann says, "It is infections that play havoc with our patients" which holds especially true of asthma.

Case No III Mrs A. A., age 70, had suffered from asthma for 20 years. During the past two years the asthma had increased in severity until it had become incapacitating and life threatening on account of impending heart failure. A careful history disclosed the fact that the onset of the asthma twenty years ago had been preceded by *extensive dental work involving devitalization of many of her upper teeth*. Changes of climate and various dietetic, hygienic, and medicinal regimes had been instituted without benefit. During the past two years her asthma had been practically constant and her condition had been made endurable only by the use of several hypodermics of adrenalin daily.

The physical examination showed a poorly nourished, elderly woman, orthopneic and cyanotic. The general physical examination revealed nothing further of marked import except a somewhat enlarged heart with a

slight systolic blow at the apex, various sized dry râles over the entire chest, slightly enlarged liver, and edema of the legs. Rhinological examination yielded nothing of significance except tumefaction of the left inferior turbinate. Radiograms in the Waters position showed moderately increased density in the floor of the maxillary sinuses, especially the left. There was marked dento-alveolar disease throughout the upper jaw with obvious involvement of the floor of the left maxillary, and possible involvement of the right.

Because the patient had suffered from asthma wherever she had lived and whatever she did, because diets had been tried and sensitization tests run by others, and because the onset of the asthma so closely followed devitalization of teeth twenty years ago, and because of such definite evidence of dento-alveolar and sinus disease on the left side, an alveolectomy with removal of the dento-alveolar disease and a Caldwell-Luc operation were done on the left side Feb 12, 1930. On account of the critical condition of the patient no work was done on the right. Twenty-four hours after the operation the patient had her last hypodermic of epinephrin for that attack which had lasted unabated for six months.

The patient is reported (March 20, 1932) as being relatively free from asthma although there has been some wheezing and shortness of breath on exertion.

Comment The past two years have been relatively comfortable for this patient. Contrary to advice the patient did not return to us for mouth work on the opposite side, but merely had the teeth extracted. This patient illustrates the important relationship of dento-alveolar disease to chronic sinusitis and to asthma via the sinuses.

Case No IV H. M., farmer, aged 70, came under observation June 23, 1930. There was nothing of significance in the past or family history. He stated that he had been quite well until three or four years ago when he noticed severe spells of coughing and shortness of breath associated with choking

spells nocturnal in type. During these times he had to be propped up in bed, for whenever he lay down he began to cough and choke. He said he had never had asthma and that he felt pretty well in the daytime but his nights were bad and dyspnea had been present on slightest exertion. There were no other symptoms of significance.

Examination showed a poorly nourished, elderly man, slightly cyanotic who choked up and coughed when he lay down. The following significant things were noted on the general examination: marked dento-alveolar infection, a moderately enlarged heart, pulse, 72, systolic blood pressure, 112, diastolic, 82, a systolic blow heard all over the precordium, musical in character and well transmitted to the axilla. There was no obvious evidence of heart failure.

Films showed very extensive alveolar disease with clouding of both maxillary sinuses, the latter corroborated by lipiodol filling defects. An electro-cardiogram showed low amplitude Q-R-S in all leads, conduction time normal, T-wave upright throughout.

Diagnosis. Extensive dento-alveolar disease, chronic hyperplastic sinusitis, asthma (?), chronic myocardial insufficiency.

Under observation in the hospital the attacks of dyspnea were largely at night and partook of the type of cardiac asthma. The urine examination was negative. Hemoglobin, 97 gms (56 per cent), red cells, 3,590,000, whites 15,000, 50 per cent polymorphonuclears. The Wassermann test was negative.

Double alveolectomy with exenteration of both maxillary sinuses produced a remarkable change in the patient's symptomatology.

Patient is reported (March 28, 1931) by his local physician as very active and reasonably well for a septuagenarian.

Case No. IV. V. H., age 16, consulted us on Jan. 3, 1930, for heart trouble. There was nothing of significance in the family or in the past history except tonsillectomy and adenoidectomy which were performed six years ago for repeated attacks of tonsillitis; there has been more or less constant catarrhal trouble for years, he has been subject to colds which have kept him out of school for weeks at a time.

Two years ago the patient had an upper

respiratory infection with bronchitis which "left his heart weak." Ever since that time he has been troubled with rapid heart action and palpitation. If he over-exercises his heart beats fast and he has a feeling of "being all in." He gets short of breath on going up hill. He also has pain and stiffness in the back at times. Recently every time he "gets bronchitis" his "heart is bad", and he has to stay in bed for weeks at a time.

The physical examination showed a well developed, well nourished lad. There was a pharyngeal lymphangitis and some enlargement of the posterior cervical glands. The tonsils were out and there was no evidence of mouth infection. The pulse rate lying was 88, sitting, 104, standing, 120. After 50 hops the pulse went to 142. One minute later it was 122 and five minutes after the 50 hops it was 106. There was no increase in the size of the heart and the sounds were normal. The systolic pressure was 135, diastolic, 85, temperature, 98.8°. There was no evidence of hyperthyroidism and the basal metabolic rate was -8. The physical examination was otherwise negative.

The urine examination was negative. The blood count was normal and the Wassermann test was negative. The electrocardiogram showed a rate of 90, R-wave upright in all leads, R-wave slurred in all leads, T-wave slightly diphasic in leads II and III. Sinus tachycardia, sinus arrhythmia.

Clinical diagnosis. Myocarditis, probably having origin in sinus infection.

A radiogram in the Waters position showed a large filling defect in the floor of the left maxillary sinus and clouding of the left ethmoids, graded ++. A rhinologic examination showed the septum deviated to the right, considerable hypertrophy of the middle turbinates, with swelling and enlargement of their posterior tips.

Operation. Bilateral in the upper part ethmoidectomy, radical left maxillary sinus exenteration, removal of middle turbinate, exploration of right middle.

Microscopically the mucosa of the maxillary sinus showed chronic inflammation with hyperplasia of the mucosa and extension of the inflammatory process into the submucosa. The mucosa of the middle turbinate showed almost total destruction of the mucosa and the underlying bone was exposed.

A report on Jan 30, 1932, states "I am in better health than since childhood I have had no bad attacks of asthma Once in a while if I run or exercise too hard in the cold I will "stuff up" for about 10 or 15 minutes At times when out in the cold or just before a storm my face hurts and I have pain between the eyes and in the cheeks" (probably ethmoid disease)

Double alveolectomy with exenteration of both maxillary sinuses produced a remarkable change in the patient's symptomatology.

Patient is reported (March 28, 1931) by his local physician as very active and reasonably well for a septuagenarian.

Case No. 17. V. H., age 16, consulted us on Jan. 3, 1930, for heart trouble. There was nothing of significance in the family or in the past history except tonsillectomy and adenoidectomy which were performed six years ago for repeated attacks of tonsillitis. There has been more or less constant catarrhal trouble for years. He has been subject to colds which have kept him out of school for weeks at a time.

Two years ago the patient had an upper

respiratory infection with bronchitis which "left his heart weak." Ever since that time he has been troubled with rapid heart action and palpitation. If he over-exercises his heart beats fast and he has a feeling of "being all in." He gets short of breath on going up hill. He also has pain and stiffness in the back at times. Recently every time he "gets bronchitis" his "heart is bad," and he has to stay in bed for weeks at a time.

The physical examination showed a well developed, well nourished lad. There was a pharyngeal lymphangitis and some enlargement of the posterior cervical glands. The tonsils were out and there was no evidence of mouth infection. The pulse rate lying was 88, sitting, 104, standing 120. After 50 hops the pulse went to 142. One minute later it was 122 and five minutes after the 50 hops it was 106. There was no increase in the size of the heart and the sounds were normal. The systolic pressure was 135, diastolic 85, temperature 98.8°. There was no evidence of hyperthyroidism and the basal metabolic rate was -8. The physical examination was otherwise negative.

The urine examination was negative. The blood count was normal and the Wassermann test was negative. The electrocardiogram showed a rate of 90, R-wave upright in all leads, R-wave slurred in all leads, T-wave slightly diphasic in leads II and III. Slight tachycardia, sinus arrhythmia.

Clinical diagnosis. Myocarditis, probably having origin in sinus infection.

A radiogram in the Waters position showed a large filling defect in the floor of the left maxillary sinus and clouding of the left ethmoid. Graded -3. A rhinocentel examination showed the septum deviated to the right, considerable hypertrophy of the middle turbinates, with swollen and edematous tips of their posterior tips.

Operation. Bilateral alveolectomy, ethmoidectomy, radical tonsillectomy, adenoidectomy, removal of middle turbinate, exploration of middle ear.

Microscopically the myocardium showed extreme diffuse interstitial inflammation, enlargement of the myocardial cells, and a moderate degree of degeneration of the myocardial cells. The inflammatory process was predominantly in the interstitium.

Chronic fibrous sinusitis, irreversible with little possibility of recovery by other than radical measures

Comment Rapid improvement followed the operative attack. At the end of two years the patient was well. He has had only occasional colds and no cardiac symptoms. The rapid cessation of symptoms and the resumption of growth and development on the part of this boy following the radical removal of the sinus infection has been striking. It is reasonable to assume that we were dealing with myocardial damage, either toxic, or from myocarditis due to actual bacterial invasion of the heart muscle, and that the focus was in the sinuses.

Case No VI F R H, farmer, aged 51, consulted us Jan 23, 1930, because of "fag". The patient had enjoyed good health until three years prior when he began to have attacks characterized by weakness, loss of appetite, soreness across lower abdomen, slight fever, a yellow sallow color and unaccountable sweating. During these attacks, which were often precipitated by changes in weather, he ached all over and there was some chilling. There has been no nausea, vomiting, excessive gas or constipation, nor mucus in the stools. These attacks have been growing in frequency and have been gradually incapacitating him. There was no history of tonsillitis or repeated upper respiratory infections. The past and family histories were of no importance and there was little history of catarrh.

The patient was a well developed, middle aged man, with a dirty, sallow, subicteric hue. He seemed exhausted. His skin was wet. The tonsils were adherent, the anterior pillars red, and pus could be expressed from the left one. There was no particular enlargement of the submaxillary glands. There was a lateral pharyngeal lymphangitis, especially on the left, but no enlargement of the posterior cervical lymphatic glands or of the thyroid. The

examinations of the heart, lungs, abdomen, rectum and nervous system were negative.

A Waters plate showed the right maxillary sinus fairly clear, left clouded (graded +3), frontals and ethinoids apparently negative. A rhinological examination showed mucopurulent secretion in the left nares and swelling of the left middle turbinate. Films of the teeth showed dento-alveolar disease and an unerupted molar on the right side, residual pathology and a partly erupted molar on the left, and probable involvement of the floor of both maxillary sinuses, especially left.

Diagnosis Focal infection with two obvious foci, tonsils and dento-alveolar disease with a left chronic hyperplastic maxillary sinusitis secondary to periapical disease.

The tonsils were removed, Jan 7, 1930. No improvement followed. Bilateral alveolectomy with resection of polypoid masses from floor of left maxillary sinus was done on Feb 20, 1930. The mucosa of the right maxillary sinus appeared approximately normal and was not resected. An x-ray film in the Waters position showed a normal left maxillary sinus shadow on April 9, 1930. During the early summer the patient felt some better but his improvement was not satisfactory. There was a return, however, of the old trouble with loss of weight, sweating, and increased fatigability in September, 1930. In December, 1930, he had a severe attack with headache, aching all over and fever up to 101°. Recently he has had a cough. There has been no pain in head, but patient feels as if he were "taking cold" with chilling at night, there has been a great deal of nasal discharge.

Rhinological examination (Jan 7, 1931) showed very definite evidences of sinusitis. A Waters' plate showed the right antrum with opacity graded +1, left, +2. Lipiodol showed considerable thickening of mucosa of right maxillary sinus and a marked filling defect of the left. Stereoscopic plates of the chest revealed nothing but the peribronchial infiltration usually associated with a chronic sinusitis. Intravenous cholecystography showed a normally functioning gallbladder.

Diagnosis Chronic hyperplastic sinusitis of both sides, recurrent on left. On Jan 14, 1931, bilateral Caldwell-Luc operations with *en masse* removal of mucosae of both

maxillary sinuses were done. The left maxillary sinus was half filled with thickened mucous membrane with polypoid hyperplasia. A pocket of pus was found in the mucous membrane in the anterior-inferior portion. The right antrum showed the same type of membrane as the left but with pus filling the entire cavity.

The patient reported well on March 23, 1931.

Comment. This patient presented an obscure diagnostic problem, infectious in origin. After removal of the tonsils without improvement, bilateral alveolectomy with removal of polypoid masses from the left maxillary brought some improvement with a normal left maxillary sinus shadow. Recurrence of the chronic hyperplastic sinusitis with polypoid masses in the left and with suppuration on the right necessitated radical procedures. A satisfactory recovery followed exenteration of both maxillary sinuses.

Case No. VII. M. C., widow, age 46, consulted us on June 19, 1930. There was nothing of significance in the past or family histories.

Present Illness. The patient had enjoyed excellent health until December, 1928, when she had influenza and was in bed five days. Her nose was stopped up, she had fever and severe headache. She had had some catarrhal trouble previously but it became much worse afterwards. Since then she has never been well. A tonsillectomy was performed, and three abscessed teeth were removed in July, 1929. The only result was a rapid increase in her weakness. In September, 1929, she was taken with terrific pains in the stomach and bowels, and was unable to sleep or eat for which she was hospitalized. Since then there have been more or less abdominal distress and insomnia. She has had night sweats. She has been constipated and forced to take almost daily cathartics. Her chief complaints were extreme weakness, pain and distress in the abdomen, headache, especially on the right side, with a sensation of pres-

sure and a feeling of fullness and ringing in the ears. She has been hospitalized three times since the onset of her trouble undergoing a rest cure and treatment of 12 weeks' duration for mucous colitis.

The physical examination showed a poorly nourished, tired appearing woman with a woe-begone, neurasthenic facies. The abdomen was diffusely tender with sharply localized tenderness without rigidity in the right lower quadrant. Otherwise the physical examination revealed little of importance. The urine examination was negative. The blood count was—hemoglobin, 12.3 gms (Newcomer), red blood cells, 3,980,000, white cells, 6,400, polymorphonuclears, 60 per cent, mononuclears, 40 per cent. The blood Wassermann test was negative. The gastro-enterological examination was negative except that the appendix did not fill with barium, the right lower quadrant of the abdomen was tender, and the colon was spastic. A rhinological examination showed no evidence of paranasal sinus trouble but a Waters' plate revealed changes in density which were confirmed by lipiodol.

On account of the possibility of a chronic appendicitis the patient was hospitalized for observation and placed on a smooth-anticonstipation regime for three weeks with little improvement in the abdominal symptoms. Radical excision of the mucosa of both maxillary sinuses was performed on July 8, 1930, (figure 9) and was followed in four months by a normal state of health. Both antra were practically filled with polypoid thickened mucous membrane. Multiple abscesses containing thick yellow pus were found in the mucosae.

The patient reported herself well on September 17, 1931.

Comment. This patient is of interest from several standpoints. (1) A text book case of (neuro) asthenia may be associated with a sinus infection. (2) Typical mucous colitis with abdominal pain, spastic constipation, may be complicated and relieved following removal of a sinus focus of infection. (3) The diagnosis of this case is

was made entirely on the clinical record with the help of roentgenograms. Examinations by two rhinologists without films brought back a report of "no material evidence for paranasal sinus pathology"

SUMMARY

1 A brief statement of sinusitis as a general medical problem has been attempted

2 Three postulates for a valid clinical answer to the question of chronic sinusitis as a source of systemic disease may be laid down, viz — (1) rigorous diagnostic surveys, (2) a technic which accomplishes a bac-

terial excision of the infected tissues, and (3) statistical studies of series of cases which satisfy the first two postulates

3 A core drill, which should help in promoting routine post-mortem examination of the sinuses has been described

4 Abstracts from the clinical records of a few illustrative cases, with comments, have been presented

We wish to express our appreciation to Drs J B Potts and W A Cassidy, rhinologists, and to Drs W L Shearer and R R Ralston, oral surgeons, for their helpful cooperation in this work

The Local and Constitutional Pathology of Bronchial Asthma*†

BY IAN G. MACDONALD, C.M., L.M.C.C., M.D.,
Ann Arbor, Michigan

G RIMM,¹ in 1925, found but thirty cases of bronchial asthma with autopsy findings and microscopic studies. Since that time, nine additional cases have been recorded by Rackemann² (one), Kountz and Alexander³ (three), Dehner⁴ (two), Steinberg and Figley⁵ (two), and Wright⁶ (one). Of this total number of thirty-nine cases, careful studies have shown² that many of the cases earlier reported were not true bronchial asthma, while in not more than twelve cases can death be said to have resulted directly from asthmatic paroxysms. Huber and Koessler,⁷ in their monograph upon the subject in 1922, presented only four cases from the literature (amongst twenty-one), and one of their own series (number 2), in which death resulted from a seizure of bronchial asthma. The remaining fatal cases are gathered from the above authors, Kountz and Alexander having the largest series of three deaths, although Rackemann reports having attended five patients in whom death was apparently due solely to an asthmatic seizure, but autopsy was not performed.

Collected from 3,690 autopsies at the Hospital of the University of Michigan since 1896, is the following series of eight cases, in five of which death can be laid to asphyxia or cardiac failure during, or immediately following a paroxysm of bronchial asthma.

In this study, attention has been paid particularly to the pathology of the individual structural layers and units of the bronchi and peribronchial tissue. For two reasons no attempt has been made to determine absolute measurements of bronchial wall thickness. (1) Many apparent fallacies render this procedure of uncertain value. The most important source of error is the wide variation in the activity of individual units of the bronchial excretive system—mucous epithelium, glands, blood vessels and capillaries. Furthermore, it is evidently quite impossible to obtain a comparable series of cross sections of bronchi from any two individuals, dependent as they are for accuracy upon the distance from bifurcations (cartilage-plaque thickness) and individual variations in structure and the varying states in which the mucosal, submucosal and muscular layers may be found postmortem as well as upon technical artifacts. (2) In spite of these difficulties, Huber and Koessler⁷ and later, Kountz and Alexander³

*From the Department of Pathology, University of Michigan, Ann Arbor, Michigan.

†Submitted for publication February 15, 1931.

were able to show quite definitely, by painstaking measurements of the bronchi of asthmatics and non-asthmatics, a thickening of the bronchial walls as a whole at certain levels, and of the individual layers, in the asthmatic individual. The uniformity of results obtained by these investigators makes certain the fact that the bronchial thickening seen grossly and microscopically, is not only apparent but real. For present purposes, then, the bronchi are divided relatively into those of small, intermediate, and large orders, those of intermediate size ranging from 2 to 5 mm in outside diameter. They were studied with reference to their respective layers, recognizing the epithelial mucosa (with goblet cells), basement membrane (upon which the former rests), subepithelial layer, musculature, glands, fibrocartilaginous layer, variable lymphoid tissue, and the vascular and nerve supply.

It is proposed not only to correlate the clinical and pathological findings in this series, but to view such results in the light of the theories of etiology in vogue at the moment. In particular, the proof for that type of asthma known as "bacterial" will be questioned. An effort will be made to review the anatomic findings in these cases with the hope of finding indications of some basic factors in the predisposition (if such there be) of the individual to allergic phenomena in general.

CASE REPORTS

Case I (Path No A-I-AI) O S, a male aged 43 years, was first a patient in the University Hospital in April, 1930, and subsequently returned for further treatment towards the end of June of that year. For five years he had suffered from attacks of paroxysmal dyspnea, increasing in frequency

and severity, and accompanied by a cough which at times was productive of a small amount of yellowish sputum. The dyspnea was inspiratory in type. The relief obtained from epinephrin was inconstant. With the periodic lessening of a chronic nasal discharge would come headaches, and more frequent and severe attacks of asthma. A thirty-pound loss in weight during the preceding year and occasional malleolar edema were noted.

Clinical and laboratory studies showed evidence of pansinusitis, nasal polypi, slight leucocytosis, a blood eosinophilia of 13 per cent, and an inconstant hypertension, as well as the classical physical signs of bronchial asthma. Sensitization tests showed positive reactions for hemolytic and nonhemolytic streptococci, and micrococcus catarrhalis from stock vaccines. Sputum culture yielded a hemolytic streptococcus, *Streptococcus viridans*, and *Micrococcus catarrhalis*. From these cultures vaccines were prepared, with which positive sensitization reactions were shown to a nonhemolytic streptococcus and *Micrococcus catarrhalis*.

During his stay in the hospital the patient was observed in many asthmatic attacks. Some were so severe as to give the impression of impending death. Such attacks resisted the administration of epinephrin, atropine, nitroglycerin, morphine, and magnesium sulphate, while those of less severity responded to the use of epinephrin. The nasal polypi were removed during April. In June the autogenous vaccine was given for a short time in repeated small injections, but during this procedure the attacks became so severe that the course had to be discontinued. On several occasions it had been noticed that severe attacks of asthma had followed the administration of coal tar products. On July 1st, one-half hour after taking 0.6 gm. of aspirin, the patient suffered a severe attack of asthma, in the midst of which death occurred, evidently from respiratory failure. Artificial respiration was of no avail although the heart sounds were audible for twenty-five minutes after the cessation of respirations.

Autopsy was performed nine hours post mortem. The body was that of a well developed, emaciated white male, 162 cm. in

length The thorax was not remarkable on external examination Upon removal of the sternum, the lungs ballooned out into the incision in close approximation A marked dilatation of the right heart was noted The right ventricular wall measured 8 mm in thickness, of which one-fourth was composed of fat The tricuspid valve admitted three fingers, and the pulmonary valve two Both valves appeared normal The left ventricular wall measured 20 mm in thickness The mitral and aortic valve orifices were of normal size The mitral valve, near the attachment of the chordae tendineae, presented indurated, nodular thickenings, and adjacent endocardial sclerosis No gross areas of fibrosis were noted The heart as a whole measured 14 by 10 by 5 cm, and weighed 280 gms The left lung measured 25 by 17 by 7 cm, and weighed 300 gms, while the right lung was 23 by 19 by 8 cm, and weighed 310 gms

The lungs were extremely voluminous Both apices presented rather firm adhesions The lungs were fully air-containing throughout, of uniform spongy consistency They cut with markedly increased resistance Both parietal and cut section surfaces were mottled slate gray in color, with some reddish coloration in both lower lobes posteriorly The large bronchi gaped widely, with evident thickening of their walls The smaller bronchi contained mucous plugs resembling tenacious jelly, and adherent in many places to the bronchial walls The trachea and main bronchi showed redness and swelling of the mucosa, with slight amounts of mucinous exudate

Further gross examination revealed no notable findings Blood culture at autopsy gave a growth of *B. pyocyanus* and *B. coli* The Kahn procedures, both diagnostic and presumptive, were negative.

Microscopic Examination Localized thickenings of the leptomeninges were noted with one area of active infiltration Most notable in the heart was a patchy fibrosis of the myocardium, with atrophy and hypertrophy of the heart muscle Endocardial sclerosis of long standing, and advanced atherosclerosis of the coronaries were additional features Small latent syphilitic lesions were present in the aorta

In general, the lungs showed a well marked emphysema, with numerous small patches of fibrosis Areas of chronic passive congestion were noted The terminal bronchioles and smaller bronchi were dilated and some of them contained plugs of laminated mucus Even the small bronchioles showed a hyalinization of the basement membrane The changes in the bronchi of intermediate size, however, were more marked A majority of these showed laminated and stratified mucus filling the lumen and constituting Curschmann's spirals The lumina were somewhat dilated, and showed frequent small saccular extensions, some of which were produced by the widening of the mouths of mucous glands The bronchi of this order also showed marked cellular infiltration of the wall which was characteristically eosinophilic and which in many areas pervaded the muscle There was only a moderate degree of hypertrophy of the muscular layer in the bronchi, but a very distinctly hyaline basement membrane The large bronchi showed changes practically of the same character as those of intermediate size The hyaline basement membrane was wide and prominent The eosinophilic infiltration extended to the cartilages, and in some instances occurred in the connective tissue on the parenchymal side of the cartilage plates There was a chronic bronchitis

The bronchial nodes showed lymphoid hyperplasia with lymphoid exhaustion The thyroid gland was deficient in colloid with microscopic evidence of Graves' constitution In accord with the persistent hyperplastic thymus the adrenals were hypoplastic and all lymph nodes hyperplastic with exhaustion of the germinal centers In the pancreas were seen areas of interstitial pancreatitis Atrophic gastropericardiac diffuse toxic fatty infiltration of the liver, and an early arteriosclerotic nephropathy were the only additional noteworthy findings

Case Summary A 45-year-old male who had "bacterial asthma" for five years, treated with autogenous vaccines, became so tired worse under their use that they had to be discontinued About three weeks before his death

sensitive to coal-tar products, he died in a paroxysm of asthma following the ingestion of a therapeutic dose of aspirin. The significant local pathological findings were (1) Hyalinization of a thickened basement membrane throughout; (2) most marked pathology in the bronchi of intermediate size, (3) occlusion of lumina by exudate, (4) eosinophilic infiltration, (5) sacculations of the bronchi, (6) moderate hypertrophy of the muscular layer.

Case II (Path No A-38-AI) S T, 75 years of age, was admitted to the Department of Internal Medicine in the University Hospital on September 3, 1930, and expired less than 36 hours thereafter. In the short history obtained, all details typical of attacks of bronchial asthma were related. These had their origin, evidently, eight years previously when working in a munition factory. There he inhaled large amounts of acid fumes, and soon began to suffer from asthmatic attacks. Latterly, suffering from constant orthopnea and dyspnea, with frequent daily paroxysms of asthma, he was admitted as an emergency after a tiring journey from his home in a distant part of the state. During the short time he was under observation, he passed from one asthmatic attack into another. A few hours after admission, his temperature was 102°, with a leucocytosis of 27,000. Signs in the chest were obscured by the intense asthma present. Twenty-four hours after admission, the patient became cyanosed, with marked tachypnea, and shortly thereafter lapsed into coma. In spite of appropriate measures, he died a few hours later.

Autopsy was performed 16 hours post mortem. The body was that of an asthenic white male, 183 cm in length. Malleolar edema was present. The thorax was flat but symmetrical, the costal angle greater than a right angle. Both pleural cavities contained about 25 cc of clear colorless fluid. There were a few adhesions, posteriorly, of each lung to the thoracic cage. The lung borders were 1 cm apart in the an-

terior mediastinum. The cardiac apex was found to be at the sixth rib in the anterior axillary line. Thymic tissue could not be seen. The heart measured 15 by 12 by 7 cm, weighed 375 gms, and appeared globular in shape, with the apex formed mainly by the left ventricle. The left ventricular wall measured 2½ cm in thickness, without gross evidence of fibrosis. Both mitral and aortic valve orifices were of normal size, with the mitral cusps showing a slight sclerosis. The right ventricular wall averaged 6 mm in thickness, one-sixth of which was fat. The ventricle was dilated, the musculature relaxed and flabby. There was slight relative insufficiency of the tricuspid and pulmonary valves.

The left lung measured 27 by 17 by 7 cm, and weighed 600 gms. The organ was markedly emphysematous. The lower lobe presented a sharply circumscribed area of bronchopneumonia. Throughout, the bronchi showed many mucous plugs blocking the lumina, and the bronchial walls showed very marked thickening. The right lung, weighing 820 gms, measured 26 by 21 by 6 cm, and presented essentially the same changes as its neighbor, with a slightly larger area of bronchopneumonia in the middle lobe. Here also the bronchi of intermediate size were thickened and filled with mucous plugs. The bronchial glands were enlarged and anthracotic. The spleen presented several small, calcareous nodules. Some perigastric adhesions were noted. In the right lobe of the thyroid was an adenoma of 15 mm diameter.

Microscopic Examination A slight myocardial atrophy and fibrosis, endocardial sclerosis and lime salt deposit in the base of the valve cusps constituted the lesions in the heart. In conformity with these changes were the aortic atherosclerosis and calcification.

In addition to an acute purulent bronchitis with acute fibrino-purulent lobular pneumonia, the lungs showed uniform emphysema and an acute exacerbation of a chronic passive congestion. The smaller bronchi were uniformly dilated, and without hypertrophy of their respective layers, or hyalinization of the basement membrane. In both the large and intermediate bronchi, but most

evident in those of large caliber, was seen hypertrophy of the musculature. In both of the latter classes of bronchi the predominant change was a thickening and hyalinization of the basement membrane. This varied in degree, and could not be said to be more prominent in one or the other class. Filling many of the larger bronchi were spirally twisted masses of mucin and fibrin (Curschmann's spirals). The bronchial outline was rendered irregular and somewhat sacculated by dilatations between the muscle bundles, and at many points this seemed to have been accomplished by taking advantage of the mouths of the mucous glands. A marked cellular infiltration about both the intermediate and larger bronchi included numerous eosinophiles. The pulmonary arteries presented a well marked proliferation of the intima, without hyaline change. There was a chronic adhesive pleuritis. In the bronchial nodes were seen, in addition to anthra-

cosis, numbers of rather recent epithelioid tubercles, without caseation. The trachea also presented a marked hyaline change in a thickened basement membrane under which were infiltrating large numbers of eosinophiles. There was, in addition, an active chronic purulent tracheitis.

A proliferating adenoma of the thyroid was accompanied by atrophy and increased stroma of the gland, with calcification of the thyroid arteries. In the spleen were several encapsulated calcareous tubercles. On the inferior surface of the liver the capsule was thickened, and there was a proliferation of the small bile ducts in the capsule, with brown atrophy of the parenchyma.

Case Summary The asthmatic condition in this case apparently had its origin in exposure to acid fumes and lasted eight years in a man aged 75 at

FIG. 1. Case II. Wall of large bronchus with hypertrophy of the musculature, thickened mucosa. Hyaline thickening of basement membrane. Section showing a mucous gland passing between muscle bundles.

death The terminal condition was that of extreme exhaustion brought on by repeated, successive seizures, on which was superimposed an acute fibrinopurulent lobular pneumonia The significant findings were (1) Hyalinization of a thickened basement membrane, (2) muscular hypertrophy most marked in the larger bronchi, (3) sacculations of the bronchi, (4) occlusion of many bronchi by exudate, (5) eosinophilic infiltration, and (6) mucous glands fairly prominent

Case III Z H (Path No A-122-AH), a male of 53 years of age, machinist, claimed that until eight months before his admission to the University Hospital in October, 1929, he had been without cardiorespiratory or other symptoms of ill-health Following an attack of influenza in the spring of 1929, periodic seizures of bronchial asthma appeared, usually nocturnal So rapidly progressive had been the course of the illness, with frequent seizures, constant dyspnea, anorexia, emaciation, asthenia, and profound general depression that in three months' time he had ceased to work and became a semi-invalid Admitted after two weeks of almost constant dyspnea and productive cough, it was found necessary to administer adrenalin or ephedrin every three hours for the control of the constantly recurring paroxysms In spite of such medication and the addition of morphia, the asthmatic attacks became more severe, and three days after admission death occurred during a particularly severe paroxysm, the patient having passed through six attacks during the previous twelve hours Laboratory studies showed seven per cent blood eosinophilia and many eosinophiles in the sputum

Autopsy The lungs were extremely voluminous, ballooning outwards when the sternum was removed Only a few apical adhesions were present on the right side There were no areas of consolidation or infarction, and no evidence of a purulent process Section revealed a striking emphysema Many of the bronchi contained plugs of mucoid, gelatinous material Grossly, there

was no notable bronchial wall thickening The lungs weighed 410 and 460 gms The thymus persisted as two well-defined lobes, each one of which measured 8 by 1½ by 1 cm The heart measured 14 by 9 by 7 cm, and weighed 335 gms The right ventricular wall, entirely muscular, measured 1 cm in thickness, with very marked right cardiac dilatation

Microscopic Examination In the heart there was a marked fatty change, subepicardial fatty infiltration, and subendocardial degenerative fatty infiltration The hypoplastic heart muscle showed a well marked brown atrophy, and there was an endocardial sclerosis of slight degree Except for the chronic passive congestion, emphysema, and numerous heart lesion cells, all the findings in the lungs centered about the bronchi The terminal bronchioles were moderately dilated In the bronchi of all degrees, but most marked in those of intermediate size, stood out a marked hyaline thickening of the basement membrane There was, however, only a slight hypertrophy of the bronchial musculature, most evident in the bronchi of intermediate size The eosinophilia was notable, infiltrating the bronchial muscle to some extent, but most striking in the bronchial lymph nodes The medium sized, and a few of the larger, bronchi showed sacculations, some of which were quite deep, each extending through an hiatus in the musculature, but with the thickened basement membrane always intact Many of the sacculations had their origin at the mouths of the mucous glands, which were quite prominent In some areas in the cartilage there was slight eosinophilic infiltration, but no destruction In many small bronchi there were plugs of fibrin and desquamated epithelium, while many of the medium-sized bronchi contained Curschmann's spirals An acute fibrinopurulent bronchitis was noted The thymus was persistent and hyperplastic with fatty atrophy

Case Summary An asthma of sudden onset such as this, occurring in a 50-year-old man, and following influenza, may be accepted as "bacterial" in origin After only eight months'

duration in which the disease fairly overwhelmed him, death occurred in an attack at the end of three days spent in the hospital, during which time he had been almost continuously in asthmatic orthopnea. The significant pathologic findings were (1) Marked hyaline thickening of the basement membrane, (2) slight hypertrophy of the bronchial musculature, (3) marked eosinophilia, seen also in the bronchial lymph nodes, (4) extensive sacculations, (5) partial occlusion of many lumina by exudate, (6) prominent mucous glands.

Case IV L. B. (Path No. A-306-AG), a 58-year-old farmer, was under observation in the medical service of the University Hospital from May 21, 1929, until his death on June 12 of that year. His chief complaint was of vague gastric distress, and secondarily of asthmatic attacks, chiefly nocturnal, for two years. Physical signs in the chest were typical of bronchial asthma. The blood eosinophilia was 12 per cent. Sensitization tests were not done. Evidence of upper respiratory infection, or of accessory nasal sinusitis, was lacking. During his stay in the hospital the patient had almost nightly severe asthmatic paroxysms, which but infrequently responded to ephedrin and adrenalin. On the day of his death he developed a severe asthmatic attack, which resisted the most heroic measures of medication, and he died after practically two hours' continuous asthmatic dyspnea.

Autopsy was performed three hours after death. On each side the diaphragm was at the level of the sixth rib. The lungs were voluminous. The thymus was well represented by fatty remains. The heart measured 13 by 10 by 4 cm. and weighed 280 gms. with a left ventricular wall thickness of 17 cm. The right heart moderately dilated showed subepicardial fatty infiltration. The lungs had a combined weight of 690 gms. and presented a striking emphysema. The thickened bronchi stood out from the cut surface with obvious narrowing of their

lumina. Apart from congestion no other changes were noted except for a moderate, generalized atherosclerosis. A culture from the heart's blood showed no growth.

Microscopic Examination The atrophic myocardium showed degenerative fatty infiltration, and there was marked subepicardial fatty change. The most marked features in the lungs were the extreme emphysema and the narrowing of the medium-sized bronchi. This latter was accomplished by infolding of the mucosa in irregular fashion, creating longitudinal rugae of varying heights. The mucosa, always intact, was thick, and beneath it there was a markedly thickened, hyalinized basement membrane present in bronchi of all orders. The intermediate bronchi showed further a thick, cellular subepithelial layer with but a slight eosinophilic infiltration. The musculature was markedly hypertrophic, but in an irregular fashion, interrupted at many points. The mucous glands were not prominent. At no point was there any marked eosinophilia. A few of the large bronchi contained granular mucinous material in small amounts with desquamated epithelium. Chronic purulent bronchitis and chronic passive congestion were the only other findings of note in the lungs.

Case Summary No evidence can be adduced in this case as to the etiology of the condition. Sensitization tests were not carried out but none of the findings clinical or pathological associate a focus of bacterial infection. In spite of the age of the patient and the short duration this case can best be attributed to an allergic factor. The following are significant pathologic findings: (1) Partial occlusion of medium-sized bronchi, (2) markedly thickened hyalinized basement membrane, (3) marked hypertrophy of the bronchial musculature, (4) extensive granular exudate in the alveoli, (5) marked eosinophilia, (6) a prominent subepithelial layer.

Case V M C (Path No A-123-AG), was a 36-year-old construction foreman who gave a definite history of asthmatic attacks occurring almost daily from 1914 up to the time of admission to the University Hospital in April, 1928. At this admission studies pointed to a "bacterial" bronchial asthma, and he was discharged with autogenous vaccines made from the strains of *B coli* and *Staphylococcus albus* to which he had shown positive sensitization tests. Readmitted in November, he reported that during the vaccine injections, the asthmatic attacks had become more frequent and more severe. The physical signs of bronchial asthma were present during both admissions. Blood eosinophilia was nine per cent. There was no definite evidence of sinus infection. Asthmatic paroxysms were frequent and severe during the second admission, with orthopnea even between the attacks. There were two to four attacks daily, responding

generally to the administration of adrenalin. On the day of death the patient passed from one paroxysm to another for six hours.

Autopsy The thorax was emphysematous in type. The heart measured 13 by 11 by 6 cm, weighed 345 gms, and showed a terminal right-sided cardiac dilatation of marked degree. The lungs showed a widespread and advanced emphysema with an area of atelectasis in the left lower lobe. The thickened bronchi stood out prominently and contained mucoid exudate. At the right base there was seen one small area of bronchopneumonia, not purulent. Mediastinal and bronchial nodes were hyperplastic.

Microscopic Examination The heart showed only extensive fatty changes. The lungs, apart from the bronchi, showed chronic passive congestion, emphysema, patches of dense fibrosis, an old area of organizing fibroid pneumonia, and one area of recent purulent lobular pneumonia. The

FIG 2 Case V Medium sized bronchus with marked hyaline thickening and folding of the basement membrane. Spiral plug of tough mucus in lumen. Marked chronic catarrh.

bronchial pathology was shown particularly by the bronchi of intermediate size, although the terminal bronchioles, in spite of dilatation, presented a marked hyaline change in the basement membrane, and the larger bronchi were thickened without the same accentuation of the basement membrane. The bronchi of medium size showed varying changes. In many the mucosa was thrown into folds of such height as to cause marked narrowing, but always with continuity of the well-marked, thickened and hyaline basement membrane except where pierced by the mouths of the mucous glands, others showed sacculations of considerable depth, and in these the mucous glands were distinctly hypertrophic. In some areas the bronchial lumina were filled with mucoid, homogeneous masses not of the Curschmann type, and poor in cells. The muscular hypertrophy was variable—quite marked in some bronchi, and almost negligible in others. A few small ulcerations of the bronchial mucosa were noted. The bronchial eosinophilia was quite striking, but there was no eosinophilia in the bronchial nodes. The main bronchi were notable in that they showed a marked hyaline change in a thickened basement membrane which extended also about the mucous glands. The thymus was hyperplastic. The liver showed healed military tubercles, and the gastrointestinal tract a chronic catarrh. An early arteriosclerotic atrophy of the kidney was present.

Case Summary. This case of 14 years' standing and said to be bacterial in origin was aggravated by the attempts to establish immunity to the supposedly offending organisms. Death occurred as a direct result of repeated seizures. The findings of interest are (1) Thickening and hyaline change of the basement membrane, (2) the varying changes in the intermediate bronchi, (3) exudate in the bronchial lumina, mucoid and homogeneous, (4) small ulcerations of the bronchial mucosa, (5) marked bronchial eosinophilia.

Case VI (Path No A-91-AI) The first admission of R. B., a 13 year old girl, was to the Pediatric Service of the University Hospital in February, 1930. Her chief complaint was 'asthma'. A paternal grandmother had suffered from hay fever. Whoopingcough and chickenpox were the only events in the patient's medical history. Since early childhood there had occurred frequent asthmatic attacks with cough and sputum. She was quite ill on admission, with marked dyspnea, musical râles throughout the chest, and no consolidation. During her stay in the hospital, she developed a lobar pneumonia with subsequent empyema, which was drained by rib resection in April. Having been discharged towards the end of May, the patient was readmitted in September for recurrence of the asthmatic attacks. During this admission the thoracic sinus became healed. She was observed in many typical asthmatic attacks. Sensitization tests were positive for a large number of animal substances, food proteins and bacteria. The attacks of asthma became more frequent and more distressing during October with an alarming increase in her previously marked asthenia. On October 18 intratracheal lipiodol injection was done, radiographic study showing slight enlargement of the right lower bronchi but no definite bronchiectasis. Following the lipiodol injection the patient complained of extreme nausea and vomited several times. She became cyanosed with gradual diminution of pulse pressure, and respiration ceased on the following day about 20 hours after lipiodol injection.

Autopsy. The thorax was opened showing on the right side a sternotomy 14 by 2½ cm. well-healed scar over the first, the eleventh rib. The lungs were extremely congested and edematous. The right pleural space was filled with pus by adhesions which presented the appearance of heavy cartilage. The sternotomy wound presented no abnormalities were present on the inside. The heart was large. Notable dilatation of the right ventricle, the left ventricle measured 7 cm. in diameter, the aorta entirely normal. The lungs measured 22 by 15 by 5 cm. and weighed 150 g.

Congestion and edema of the lung parenchyma were noted. The small bronchi showed moderate dilatation, the larger bronchi hypertrophy, and the lumina of the latter a tenacious, mucoid exudate. The right lung was slightly smaller in volume, 18 by 12 by 8 cm, but weighed 740 gms and showed marked edema. In the main bronchus was found a tough fibrinous membrane forming a complete cast extending into the bronchi of the second order. In the intermediate bronchi were found many plugs of mucoid exudate, while the smaller bronchi were dilated. In the larynx and trachea the mucosa was covered with a mucopurulent exudate.

Microscopic Examination Atrophy of the heart was apparent, with Zenker's necrosis, fatty degenerative infiltration of the myocardium and relative increase in stroma. The aorta was hypoplastic, the pulmonary artery, slightly atheromatous. In general, the lungs showed chronic passive congestion with an acute exacerbation and edema. Curschmann's spirals were present in many of the bronchi. The bronchi of intermediate size showed the most marked thickening of the bronchial wall, especially muscular hypertrophy with eosinophilic infiltration. Hyaline thickening of the basement membrane in the bronchi of all sizes, even those of less than 1 mm outside diameter, was marked. The large bronchi were without the same degree of thickening presented by those of medium size. Superimposed on these changes was an acute purulent bronchitis and a hyperplasia of the mucous glands. Both in the bronchial lumina and throughout the lung were numerous oil droplets which had not given rise to any reaction. The bronchial nodes were infiltrated with eosinophiles. Except for hypoplasia of the adrenals equivalent to that of the aorta, there were no other notable findings.

Case Summary This child had suffered from asthmatic attacks for many years and it should be noted that sensitization tests, carefully carried out, indicated that she was hypersensitive to several types of allergens. In conformity with this, it is a reasonable con-
 jec-

ture that her death was due to an allergic reaction to lipiodol. Of note in the pathologic findings are: (1) A marked hyaline thickening of the basement membrane comparable to that found in the preceding cases; (2) distinct muscular hypertrophy in the bronchi of medium size; (3) distinct eosinophilic infiltration of the bronchial walls and of the lymphnodes, (4) hyperplasia of the mucous glands.

Case VII S K (Path No A-343-AH), a white male of 56 years of age was first admitted to the University Hospital on April 25, 1930. His chief complaint was 'asthma', which was of three years' standing, and the onset of which he attributed to the forced inhalation of fumes from the spraying of lacquer paint in the factory where he was working. With the asthma there occurred swelling of the face and feet, palpitation, and two months later, hay fever, which was shown by sensitization tests to be due to ragweed. Two sinus operations were followed by pneumonia which confined him to bed for 14 weeks. A course of 'injections' was given with no benefit. The hay fever recurred each summer, the asthma, palpitation and edema became worse as time went on, and there were frequent attacks of abdominal colic. In the family history, the mother had had asthma, while other immediate relatives had suffered from rheumatic conditions, tuberculosis, and cancer. When admitted the patient was extremely weak, in an asthmatic (cardiac?) condition, but during his stay in the hospital he suffered many typical asthmatic paroxysms. The blood eosinophilia was six per cent. Acute abdominal pain was a frequent complaint, for which no cause was determined. A rapidly developing pneumonia in the right lower lobe caused death on May 8, 1930.

Autopsy The body was dolichomorphic in type, with evidence of recent loss of weight and the appearance of premature senility. The lungs were voluminous, filling the anterior mediastinum, and the cardiac apex was at the level of the fifth rib, inside the midclavicular line. The heart, except for

some atherosclerosis of the aortic cusps, and terminal right-sided cardiac failure, was not remarkable. The lungs together weighed 1260 gms, the right lower lobe showing practically complete consolidation. The left lung, extremely voluminous, presented marked thickening of the bronchial walls, which projected above the cut surface of the organ. Splenic, hepatic, mesenteric and peritoneal tubercles of varying ages were found.

Microscopic Examination The heart, in addition to subepicardial fatty change, showed marked endocardial sclerosis and fibrosis extending into the myocardium. The coronaries were markedly sclerotic, without obliteration. Extensive areas of croupous pneumonia in the right lower lobe showed partial organization of the fibrinous plugs in many alveoli. The emphysema was patchy and there was an acute exacerbation of a chronic passive

congestion. All of the bronchi showed the changes characteristic of bronchial asthma. The medium-sized bronchi in particular had a hyaline basement membrane of unusual thickness. Most of the bronchi were filled with a tough mucin. There was an irregular folding of the mucosa of each of the bronchi as well as many sacculations which not infrequently passed entirely through the musculature at the mouths of the mucous glands. The bronchial musculature was very hypertrophic, and in a remarkably uniform fashion. The eosinophilic infiltration was less marked than that seen in the other cases with the same degree of alteration of the mucosa, and there were no eosinophiles in the bronchial nodes. Acute purulent bronchitis and areas of bronchopneumonia completed the pulmonary pathology. In the bronchial nodes were encapsulated, caseating tubercles. Generalized atherosclerosis ar-

FIG. 3. Medium sized bronchus with hyaline thickening of basement membrane and a localized area of metaplasia of ciliated columnar cells to a more cuboidal type. Changes characteristic of bronchial asthma.

teriosclerotic nephropathy, and fibroid atrophy of the testes were noteworthy findings

Case Summary This case resembles number II of the series in that the onset of the asthma was attributed to the inhalation of chemical fumes, with the subsequent establishment of a diagnosis of hay fever on a protein-allergic basis occurring at intervals, concomitantly with the asthma. As a further contribution towards possible etiology is the record of two (evidently) radical sinus operations. Further should be noted the 19 weeks' illness with 'pneumonia' and the absence of benefit from 'injections'. Pathological features of interest are (1) An unusually thick, hyaline basement membrane, (2) the presence of mucosal foldings, as well as many sacculations, (3) marked uniform hypertrophy of the bronchial musculature, (4) slight degree of eosinophilia, (5) mucinous exudate in the bronchi, (6) hyperplasia of the mucous glands

Case VIII S A (Path No A-142-AG), a 58-year-old white female admitted to the Gynecology service of the University Hospital in 1927 for vaginal bleeding, had suffered from asthma since the age of 13. She had had pneumonia at least four times. The asthmatic attacks had increased in frequency in the preceding few years. In 1928, following irradiation for a pelvic neoplasm at intervals during the year, she returned to the hospital critically ill and died in a few hours.

Autopsy There was a remarkable facial hypertrichosis, although the body hair was normal in distribution and amount. Lung borders were 2 cm apart in the anterior mediastinum. Areas of lymphoid tissue were apparent in the thymic fat. The heart presented a distinct relative right-sided preponderance (right ventricular wall, 11 mm thick, left, 17 mm), and a terminal right-

sided failure. The lungs showed purulent bronchopneumonia. There was an apparent increase of fibrous tissue along the bronchial tree and many of the bronchi were dilated. There were adenomas in the thyroid gland. In the body of the uterus there was a sloughing, neoplastic mass with much scar tissue adjacent to it.

Microscopic Examination Diffuse fatty change and endocardial sclerosis were seen in the heart with slight localized fibrosis of the myocardium. The lungs showed an acute purulent bronchitis with acute purulent bronchopneumonia. In areas there was a marked hypertrophy of the bronchial epithelium, amounting in places to a metaplasia to a stratified type. Quite as prominent as this was the almost universally thickened and markedly hyalinized basement membrane. The bronchial lumina varied widely in configuration—some quite regular, others presenting extensive sacculations, often through the musculature, but always with continuity of the basement membrane. The subepithelial layer was moderately thickened. All the bronchial lumina were widened. The muscular layer was distinctly hypertrophic. In none of the bronchi, or any of the lymph nodes, was there any degree of eosinophilia. The greater part of the body of the uterus was replaced by a peritheliomatous angiosarcoma, probably arising in a leiomyoma.

Case Summary The interest in this case lies in the duration of the disease—45 years. The age of onset and the absence of foci of infection would indicate that this case did not belong to the class of bacterial asthmas. In view of the long standing pulmonary disease, the following are of interest: (1) Marked hypertrophy of the bronchial epithelium, (2) universally thickened and markedly hyalinized basement membrane, (3) distinct hypertrophy of the bronchial musculature, though not greater in degree than in some of the preceding cases, (4) extensive sacculations of the bronchi; (5) moderate thickening of the subepithelial layer;

- (6) widening of all the bronchial lumina, (7) absence of eosinophilia

DISCUSSION

From a clinical viewpoint in each of these eight cases the criteria of bronchial asthma were established. Five of them died from the immediate results of asthmatic paroxysms. In the last three cases the cause of death was intercurrent infection or neoplasm, thus making possible a contrasting study with those in which the asthmatic phenomena were predominant at death. The duration of the disease in this series of cases varied from eight months to 45 years, the age of the patient from 13 to 75 years. According to the classi-

fication still employed clinically cases I, III and V would be termed 'bacterial' while cases II, IV and VIII probably conform to the negative appellation of one writer—'non-bacterial allergic asthma'. In the remaining two cases sensitization tests and clinical evidence make it clear that the individual was not only hypersensitive to certain allergens but also had foci of infection usually accepted as being of paramount importance in 'bacterial' asthma.

The clinical evidence of bronchial asthma and its periodic dramatic crises with which the older writers were mainly concerned are too well known to bear repetition. It should be re-

FIG. 4. Medium sized bronchus from case of bronchial asthma. The wall is thickened by inflammatory infiltration. Many of the cells in this infiltrate are eosinophilic.

teriosclerotic nephropathy, and fibroid atrophy of the testes were noteworthy findings

(6) widening of all the bronchial lumina, (7) absence of eosinophilia

DISCUSSION

From a clinical viewpoint, in each of these eight cases the criteria of bronchial asthma were established. Five of them died from the immediate results of asthmatic paroxysms. In the last three cases the cause of death was intercurrent infection or neoplasm, thus making possible a contrasting study with those in which the asthmatic phenomena were predominant at death. The duration of the disease in this series of cases varied from eight months to 45 years, the age of the patient from 13 to 75 years. According to the classi-

fication still employed clinically, cases I, III, and V would be termed 'bacterial', while cases II, IV, and VIII probably conform to the negative appellation of one writer—"non-bacterial allergic asthma". In the remaining two cases sensitization tests and clinical evidence make it clear that the individual was not only hypersensitive to certain allergens but also had foci of infection usually accepted as being of paramount importance in 'bacterial' asthma.

The clinical evidence of bronchial asthma and its periodic dramatic crises with which the older writers were mainly concerned are too well known to bear repetition. It should be re-

FIG 4 Medium sized bronchus from case of bronchial asthma, showing hypertrophy of the smooth muscle in the wall. Hyaline thickening of basement membrane and cellular infiltration. Many of the cells in this infiltration are eosinophiles.

marked, however, in support of the statement of Huber and Koessler,⁷ that the coincidence of blood and sputum eosinophilia is pathognomonic of the disease, pulmonary distomiasis and hydatid disease alone excepted

Constitutional Pathology

In reviewing the gross and microscopic findings in these cases, one is impressed by certain constantly recurring evidences of constitutional pathology. These center about the lymphoid apparatus and the chromaffinic and vascular tissues. Table I (p 272) shows the remarkable manner in which all these cases conform in essential detail to the state known as the thymico-lymphatic constitution. Many of these cases, in spite of the fact that all had reached middle age except one child of 13, showed well-defined thymic remains even grossly, while all but one showed microscopic evidence of general lymphoid hyperplasia. Every case presents hypoplasia of the adrenals and of the aorta. As to physical habitus some of these patients were of the asthenic dolichomorphic type of the thymico-lymphatic constitution while others were of the gouty-arthritic habitus.

Local Pathology

Dealing with the local pathological changes, the microscopic features of the bronchial and peribronchial tissues are of the greatest interest. Most constant are those occurring in the basement membrane. In this series, variable as it is in respect to apparent etiology, age of the patients, and duration of the disease, the basement membrane changes are striking in their uniformity. These are two in number,

thickening and hyalinization, as first noted by Monckeberg.⁸ Which is primary cannot be said with certainty, for both are well marked in the case of only eight months' standing. Always marked in the intermediate bronchi, these changes may extend into the smallest bronchioles, and in certain instances are most extreme in the large bronchi. The absolute and unvarying continuity of the membrane changes no matter how extensive the sacculations, or how high the mucosal rugae, is a matter of note. For many years this basement membrane change has been recognized in this laboratory as an invariable finding in asthmatic conditions. How advanced this change may become is illustrated by case V, of 14 years' standing, in which the thickened and hyaline basement membrane in the main bronchi extends even about the mucous glands (figure 2). This case is also of interest in showing small ulcerations of the bronchial mucosa—a finding previously noted by Kountz and Alexander³ and Berkart.⁹ In the other case of long duration (number VIII, 45 years), the epithelium presents a marked hypertrophy. Increased cellularity has led to some increased thickness of the subepithelial layer in practically all the cases, but is most evident in case IV. In this layer the eosinophilia, when present at all, is generally most prominent.

Second only to the basement membrane change in constancy, is the hypertrophy of the bronchial musculature. That the degree of hypertrophy is not proportionate to the duration of the disease is shown by the fact that case IV two years after onset has the most marked muscular hypertrophy which

far outshadows that seen in case VIII after 45 years of asthma. In accord with this is the finding of only an irregularly distributed muscular hypertrophy in case V of 14 years' duration, while case III after eight months presents a uniform hypertrophy of slight degree. It is therefore quite evident that some other factor or factors must enter into the mechanism of the asthmatic orthopnea.

Einthoven¹⁰ first proved (1892) by experiments later duplicated by Brodie and Dixon¹¹ (1903), that stimulation of the peripheral end of the vagus in itself was sufficient to produce stenosis of the bronchi, due to a contraction of the muscle fibers. Dixon further found that the same phenomenon occurred in a decerebrate animal by irritation of the nasal mucous membrane. In 1909 Monckeberg⁸ first noted histologically an hypertrophy of the bronchial musculature in an asthmatic, and this, together with Auer's statement¹² that the anaphylactic process takes place in animals in which the vagus nerves had been cut long enough to produce degeneration of the nerve endings, not only enabled Meltzer¹³ to explain asthma on the basis of allergy, but apparently vanquished those proponents of the "mucosal edema" theory of bronchospasm, who stressed the activity of the bronchial exudative system (*Vide* Faschingbauer,¹⁴ Unverricht¹⁵). In the experimental animal, peripheral vagal stimulation doubtless produces preeminently a spasmodic contracture of the bronchial musculature, but the analogy to the asthmatic state is only apparent, and modified by many other factors, intrinsic and extraneous. Experimental proof is not lacking that vagal stimu-

lation produces in addition vasodilatation, and that the nerve carries secretory fibers to the bronchial glandular system. In the asthmatic individual on an allergic or other basis, with the chronicity of the condition, and probably some degree of chronic infection superimposed, it is apparent that the neurogenic substrate is much altered as compared to the experimental animal. With this much evident, reference to cases III, IV, V, and VIII makes it apparent that the histopathology taken in correlation with the clinical course of these cases substantiates the suggestion of Alexander¹⁶ that the bronchoconstriction is in reality due to a combination of all the effects of peripheral vagal stimulation, namely muscular contraction, vasodilatation, and glandular secretion, with one or the other assuming the dominant rôle in the individual case. The argument as to the respective importance of the muscular contraction and the "mucosal edema" is therefore quite pointless.

In conformation with this is the varying degree of hyperplasia and prominence of the mucous glands. In case IV, which presented the most marked muscular hypertrophy, the glands were atrophic.

The frequency of tissue eosinophilia in asthma has long been recognized, and the nature of the eosinotactic stimulus a point of controversy. In five cases of this series the eosinophilia was a notable feature, its absence in two of the remaining three is possibly to be accounted for by the presence of superimposed predominant pulmonary infection which overshadows the asthmatic process. The degree of eosinophilic infiltration was highly variable. Several

cases showed infiltration of the bronchial musculature and, to a slight degree, even of the cartilage, but in none was there the erosion and destruction of cartilage noted by certain observers.³ The subepithelial layer contained the largest number of eosinophiles, but they may be spread outside the cartilage and be prominent in the peribronchial tissues. In cases III and VI the bronchial lymph nodes were remarkably infiltrated. Clinically, the blood eosinophilia is a most constant feature in this series, ranging from six per cent to thirteen per cent. One author,⁵ in attempting to differentiate the histopathology in "bacterial" and "non-bacterial allergic" asthma, has made the claim that eosinophilia is practically absent in the former, and constant in the allergic type. All three of the present cases that could be considered "bacterial" showed a marked eosinophilia, even infiltrating the muscle and bronchial nodes in case III, while case IV, which was without suggestion of bacterial etiology, showed only a slight eosinophilia although dying in an asthmatic crisis.

Although founded on the postulates laid down by such observers as Virchow, Marchand, and Ribbert (perivascular lymphoma), the conception of true autochthonous tissue eosinophilia cannot be accepted. The massing of the eosinophile cells varies in location from subepithelial to peribronchial layers, may be absent at some points, occurs in the bronchial nodes, and in the spleen and thymus (Huber and Koessler), and in some cases the eosinophiles can be seen in great numbers about the bronchial capillaries. Schlecht first proved (1910) that blood eosinophilia occurred regularly

as part of the anaphylactic process upon reinjecting sensitized animals. Recently Unverricht¹⁵ drew attention to the fact that Schilling has proved definitely the production of eosinophiles in the bone marrow, their entrance into the blood stream, and their mobilization in the lungs from the blood in the anaphylactic animal. Moreover, the eosinophiles were found to disappear wholly from the circulating blood at the onset of the anaphylactic seizure, subsequently reappearing and becoming more numerous. Upon extirpation of the spleen or its exposure to x-ray, the eosinophiles in the circulating blood were increased, whereas, conversely, the injection of splenic juice caused a reduction of the blood eosinophilia. The eosinophilic increase, then, in the circulating blood and tissue is most reasonably regarded as a generalized hematopoietic response, designed for protection against the foreign allergic substance, be it bacterial, peptone, amine or chemical, but acting as an eosinophilotactic stimulus. Its absence is generally due to some superimposed infection which assumes dominance, and in response to which the leukopoietic function is altered. This has recently been proved by the work of McGregor on experimental sinus infection in animals, in which the introduction of a fresh infection caused the complete disappearance of eosinophiles from the tissues in a relatively short time.

In the guinea pig dead from an anaphylactic shock, the classical picture in the lung fields is the almost absolute stenosis of the bronchi due to obliteration of the lumen by infolding of the epithelium and contraction of the muscular layer. This has never

been exactly duplicated in man, although in one case reported by Bough-ton,¹⁷ dying after the injection of 1 minim of horse serum, the microscopic picture in the lungs was very similar to that seen in the sensitized guinea pig. The opposite, however, is seen in most of the reported cases, as in this series, in which the most frequent finding is extensive sacculation interrupting the continuity of the muscular layer and extending through the mouths of the mucous glands, the latter evidently offering the necessary hiatus for the extension of the sacculations. Illustrating again the inconstancy of the bronchial changes is case V in which the bronchi in some instances present a mucosal infolding and partial stenosis suggestive of the anaphylactic guinea pig, while others are widely dilated with extensive sacculations—both of these occurring in a supposedly 'bacterial' type of asthma. Only in case IV (allergic?) is narrowing and stenosis of the bronchi at all generalized, although in two of the other cases, V ('bacterial'), and VII (doubtful etiology), the bronchi are much narrowed in some areas. In these three cases the bronchial stenosis has evidently been accomplished by infoldings and muscular spasm with exudate in the lumina playing a lesser part. In other cases the occlusion of the lumina is accomplished by the exudative products of the hyperplastic, bronchial mucous glands and mucosa (Curschmann's spirals, cellular debris). In practically all instances the smaller bronchioles are uniformly dilated, obviously the result of increased intrabronchial tension, which is in all probability also the cause of the bronchial sacculations. Of all the foregoing

changes it should be remarked that their variation in distribution is such that many fields have to be examined before one can come to definite conclusions regarding the type of pathologic change predominant.

The study of the cardiac changes becomes of interest in the light of the claim made by Alexander *et al*,¹⁸ that the heart remains remarkably free from damage in long continued bronchial asthma. They established the criteria of bronchial asthma in 50 patients with a ten year average duration of the disease and found only four with any clinical evidence of cardiac impairment that could be attributed to the asthmatic condition. They suggested that the increased intrathoracic pressure impedes the return of venous blood to the heart, thus leaving less work for the heart to accomplish during an attack. This is not borne out by the almost constant ventricular hypertrophy in this series at autopsy. Including a 13-year-old girl, and without note of sex or build, the average thickness of the left ventricular wall in all eight cases was 18.25 mm, and of the right ventricular wall 7.87 mm. The case of longest duration (VIII) presented a distinct right-sided preponderance with a right ventricular wall of 11 mm thickness. In spite of the fact that in each case the right ventricular wall is at least slightly increased in thickness, in only one (IV) is there any definite increase in subepicardial fat, while in two (III and VI) it is entirely muscular. Valvular lesions were lacking. The chief changes are atrophy, myocardial fatty infiltration, and patchy myocardial fibrosis.

Recent writings have referred to the

absence of associated tuberculosis,^{15, 20} often mentioned by the older writers. Only three of our cases showed tuberculous lesions and these consisted of old healed tubercles in the bronchial nodes, and in the liver in one instance.

Etiology

Until the conception of allergy became applicable to asthma, all investigators directed their attention to the determination of the inciting factors producing the periodic, dramatic crises with which they were called upon to cope. It was Ehrlich's pupil, Otto, who published in 1906 the first systematic investigations and conclusions regarding anaphylaxis. Four years later Meltzer¹⁸ suggested that asthma was an anaphylactic phenomenon, and that all asthmatics were sensitized to a specific substance. Forthwith a multitude of inciting factors were taken as proven, and the vial and needle of the immunologist became the chief weapons of the clinician against asthma. With von Pirquet's conception of human allergy, as contrasted to experimental anaphylaxis, certain factors were found necessary to establish the proof of a substance acting as an allergen, viz (1) An exact anamnesis, (2) a positive cutaneous reaction, (3) the passive transference of the cutaneous reaction to a healthy person by the serum of the allergic patient (Prausnitz-Küstner reaction), (4) the proof of the existence of the allergen in the individual's environment, (5) reproduction at will of the allergic phenomena by exposure of the unprotected patient to the allergen, by inhalation, ingestion or injection; (6) disappearance of the symptoms by removal of the offending allergen. It

soon became evident that only a small percentage of the cases studied were truly allergic, and for the susceptibility of the allergic individual, Coca²⁸ invoked the existence of an unknown immune body—the atopic reagent.

A variety of conditions thus became known as allergic manifestations—serum disease, hay fever, urticaria, certain types of enteritis and eczema, migraine, as well as bronchial asthma. In spite of the cases of asthma in which all the above postulates have been fulfilled, and many with apparent cure by reinjection of the specific allergen in desensitizing doses, there remain many cases in which none of the multitude of known allergens can be shown to be causative. And there are other findings which would indicate that there are more important, basic and underlying factors of which allergy is but an expression. Although only ten per cent of individuals are allergic in the ordinary sense of the term, Bloch and Karner²⁰ demonstrated that practically any subject could be forced to allergic reaction, many bronchial asthmatics exist constantly in an environment laden with the specific allergen to which they are sensitive, and yet react only at irregular periods, many others, contrariwise, after removal to surroundings supposedly free from the causative factor do not necessarily improve and may even become worse; and finally, the proof is now overwhelming that the allergic substance, whatever it may be, is not necessarily protein in nature. Proof of this is found in the production by a non-protein extract of ragweed, of allergic phenomena exactly duplicating those ordinarily seen in cases sensitive to this plant.

An illustration of the latter, also, is the large group of cases showing susceptibility to chemical agents. Chief among this group are the coal tar derivatives—salicylic acid and its various derivatives and modification, antipyrin, methyl salicylate, benzoic acid and sodium acetate. Case I of this series, in spite of a 'bacterial' type of asthma, showed a definite susceptibility to, and severe paroxysms following, the administration of acetylsalicylic acid, death occurring in a seizure so induced. Van Leeuwen¹⁹ reports a similar case of susceptibility to acetylsalicylic acid manifested by severe asthma suddenly developing in a woman who had taken the drug for years previously, and also cites the case of another asthmatic who was susceptible to antipyrin. He concludes that such hypersensitiveness is acquired through absorption from the gastrointestinal tract, with altered reaction to the molecule as it is in the blood stream. In the case of sudden death reported by Wright,⁸ the asthmatic seizure commenced a short time after the administration of acetylsalicylic acid and codeine. Like van Leeuwen's case, adrenalin was ineffective. By no stretch of imagination can such results be interpreted as due to the actual toxicity of aspirin. This has been determined by de Jankovich,²¹ who reported six cases of fatal poisoning with the only notable autopsy finding that of multiple hemorrhages, and fixed the lethal dose at 20 gms.

It is therefore evident that even as the atopic reagent in the hypersensitive individual is unknown, so is the specificity of the allergic antigen a matter of doubt. The basic laws of immunology demand that to establish the iden-

tity of a specific allergic reaction, the experimental repetition of passive sensitization with an antibody-containing serum must be proven. The inability to obtain such a reaction with many supposed allergic antigens makes it impossible to apply the general principles of so-called protein anaphylaxis to other forms of hypersensitiveness.

For this reason it seems impossible to accept as proven the conception of bacterial protein acting as a basic, allergic, etiologic factor to produce a clinical entity known as 'bacterial asthma'. Introduced by Walker²² in 1917, the term was immediately adopted by clinicians as a most opportune label for those asthmatics who did not react to any known allergen, and in whom one could demonstrate the presence of focal infection, preferably in the accessory nasal sinuses, or existing as a chronic form of bronchitis. As early as 1922, Cooke,²³ in a critical review of Walker's work showed that the latter had demonstrated clinical improvement under nonspecific bacterial vaccine treatment, regardless of the reaction obtained with the bacterial protein used. Walker's results showed no conformity with local cutaneous reactions or recovery of specific organisms in the vaccines. Many of his best results were obtained with *Staphylococcus aureus* vaccine, although that organism had not been recovered. Cooke, in 50 cases of bronchial asthma, found only two which reacted to any type of organism with an immediate urticarial wheal, and even in these the bacteria to which they thus appeared sensitive could not be recovered from the sputum or nasal cultures. He was quite unable to elicit any constitutional re-

actions by the use of bacterial preparations as allergens, and concluded that they do not act as fundamental allergens *per se*, that the cutaneous test with bacterial preparations was useless, and that the conception of bacterial asthma was based entirely on analogy Six year later, Zinsser²⁴ supported these conclusions and confessed to knowing of only one case where eradication of a sinus infection associated with bronchial asthma gave relief Unger,²⁵ reporting 189 patients with bronchial asthma and hay fever treated by sensitization tests and injections in the clinic at Northwestern Medical School, is silent regarding any results with bacterial reactions or vaccines It is a fact worthy of note that the cases in this series who received treatment with supposed specific vaccines uniformly became much worse, one case, during such treatment passing into a prolonged series of seizures that eventually resulted in death (case V)

The case against the specificity of bacterial allergens becomes even more

convincing through the lack of any uniform pathological changes in the asthmatic so classed in spite of effort to establish such an entity In a recent publication, Steinberg and Figley,⁵ on the basis of autopsy findings in two cases attempted to differentiate the pathologic changes in 'non-bacterial allergic' and 'bacterial' asthma, referring particularly to the contrasts in emphysema, atelectasis, bronchial exudate, muscular hypertrophy, destruction of epithelium, and eosinophilia in the two types Tables I and II show how variable the changes are in both types This has been discussed already in regard to the eosinophilia, the epithelial destruction is more likely an evidence of activity of the process, while the other changes seem to vary in individual response, irrespective of etiology

It is evident at least that in spite of the apparently well defined relation of the disease to allergy in a few cases, in the majority of instances we are without definite knowledge as to the underlying factors of asthmatic etiology. As

to the actual inciting factor of the individual paroxysm, we are no nearer the truth than were the disciples of the school of Salerno, nor are we able to describe the dramatic phenomena in such graphic phrases as did Floyer in 1698. In general one can say that the symptoms are equivalent to an expression of hyperstimulation of the parasympathetic nervous system. Hansen,²⁶ in addressing the Royal Society of Medicine in 1929, correlated this fact with the conception of the psychophysical coordination of the individual by which the autonomic and vegetative nervous systems function in harmonious interrelation. Thus, by the reaction of the higher centers upon the more lowly neurogenic system, can one perceive some reason for the well established cases of asthma constantly exposed to the inciting allergen, but in whom the asthmatic paroxysm occurs generally after periods of mental stress.

Even with this rather vague hypothesis as a reason for onset in some cases, even with the possibility of van Leeuwen's late theory of 'colloid substances of unknown composition in the atmosphere', one is driven to seek a deeper anatomic substrate upon which these inciting factors act. In such a search, first of all, one is confronted by the frequent repetition of a familial history. The heredity of the allergic soil is a well known and established fact. In addition, the asthmatic, as Davidson²⁷ points out, often gives a family history not only of asthma, hay fever, urticaria and other definite allergic phenomena, but also nervous manifestations such as migraine, epilepsy, hysteria and other neuroses. The majority of cases of true asthma occur in middle

aged people who show prematurely a degenerative reaction to the stress and strain of living, often with accompanying chronic bacterial infection, focal or otherwise. Such lowering of vital force is evidenced in several of the cases in this series by repeated and prolonged infections which in themselves would have been but transitory with the normal individual.

Seeking more definite anatomic and histologic evidence of deviation from the accepted normal, each case in this series shows conclusive evidence of a pathologic constitution. Table III shows the evidence of such in the lymphoid and chromaffinic tissues and in the vascular system. The thymicolymphatic constitution, persistent in later life, provides that receptive anatomic substrate in which the so-called allergic antigen is best able to elicit those diverse phenomena known as allergic reactions. It is reasonable to suppose that our designation 'allergen' may be applied in most instances to any substance which possesses the ability of acting upon this pathologic constitution in such a manner as to provoke an expression of its altered state. More specifically, the allergic state is an altered reaction, but it is the altered reaction of this inheritable, hypoplastic type of constitution often associated with an exudative diathesis, and upon which a multitude of exogenous, provocative factors, ordinarily without influence on a normal soil, are capable of producing the expressions of the diseased state. Such an individual may reach middle life before showing definite pathologic evidence of his constitution, and then, as in case III, under some added load as an acute infection,

TABLE III
Presumable Etiology and Cardiac Condition

inhalation of chemical fumes, or mental stress, may suddenly exhibit a profoundly altered reaction which may be so constantly severe and depressive as to bring about dissolution in a comparatively short time.

SUMMARY

1 Eight cases of bronchial asthma with autopsy findings and microscopic studies are reported. In five of these death resulted during asthmatic paroxysms.

2 The chief local pathologic changes are—

- a Invariable thickening and hyaline change of the basement membrane of the bronchi
- b Eosinophilia.
- c Varying degrees of muscular hypertrophy and glandular hyperplasia dependent upon

the individual reaction to vagal (?) stimulation

d Bronchial sacculations occurring through the mouths of the mucous glands.

e. Epithelial changes such as hypertrophy and metaplasia, interpreted as evidence of chronicity.

3. Review of clinical, immunological and pathologic evidence fails to support the conception of such an entity as bacterial bronchial asthma.

4 Each of the cases of this series is proven to be of a thymicolymphatic constitution. It is suggested that bronchial asthma and many other 'allergic' phenomena are but the expression of the response of this inheritable constitution to exogenous substances—'allergens'

Chronic Appendicitis*

BY HARRY C. SALTZSTEIN, M.D., *Detroit, Mich*

MORE half hours may be spent puzzling over whether to operate for chronic appendicitis or not than over any other major surgical condition. By the time a patient with gallbladder disease consents to operation, the symptoms are usually definite, and in the great majority of cases there have been sharp colics. Those suffering from goiter usually wait until they are nervous and have lost weight before consulting a surgeon. Patients with cancer or with peptic ulcer usually have well defined clinical pictures by the time of operation. On the other hand, the public is so well informed and apprehensive of delay in appendicitis that patients usually seek operation immediately if appendicitis is diagnosed.

Discussion will be limited to chronic appendicitis—with pain, usually of long duration, either repeated or persistent, in the right lower quadrant, with no rise in temperature nor leukocytosis.

DIAGNOSIS

There is a voluminous literature, which I will not attempt to review. Each year brings forth its quota of critical analyses of cases, positive opinions or impressions, diatribes against appendectomy unless that organ be acutely inflamed, etc.; and if one

glances over several of these, or some of the reviews, he will be surprised at the wide differences of opinion still existing as to the indications for what is apparently one of the simplest operative procedures we do. On one side is Carnett¹ who states that "there is no such clinical entity as chronic appendicitis", and that pain in the right side is very frequently due to intercostal neuralgia, which can even simulate acute appendicitis. On the other side are several noted internists as Rehfuess and Boas, surgeons as Deaver, who, while picking their cases carefully and refusing to operate upon or have operated upon the majority of those complaining of right sided pain, nevertheless state positively that appendectomy does cure chronic pain in the right side, even chronic pain in the upper abdomen with right lower quadrant tenderness; and that sometimes the diagnosis is most difficult, being made only after right lower quadrant exploration, and then is not definite until one has followed the patient and he remains free from pain. Gaither,² in a careful review based upon 1,000 cases, concludes that "chronic appendicitis is at the present day a widespread and often unrecognized malady, it is often masked by the prominence of its secondary manifestations, it should be thought of in all cases of disordered digestion presenting motor and

*Received for publication, August 25, 1931

secretory symptoms, in every case of chronic constipation, in gastric upsets without definite ulcer symptoms, in intestinal dyspepsia and toxemic states"

Figures can easily be obtained showing that to operate, or not to operate, for chronic appendicitis is indeed a major problem

Lichty,³ analyzing 517 consecutive cases in which "the complaints after the operation were the same as before the operation", found that in 243, or almost one-half of them, appendectomy had been performed for chronic appendicitis. Andresen⁴ found that ten per cent of the total admissions to his gastro-intestinal clinic at the Long Island College Hospital had had an appendectomy, and that among similar cases in private practice there were 13 per cent who had had appendectomy. Others have put this figure as high as 25 per cent

There is no doubt but that many appendectomies are part of a long chain of useless and now discarded operations. These started with ovariectomy, then included operations for retrodisplaced uterus, chronic salpingitis, adhesions, various uplifts for neuralgia, as movable kidney, ptotic stomach and bowel, chronic cholecystitis, finally reaching the appendix. Indeed, these procedures have in the past all been done for this same chronic abdominal pain, generally right sided. But there is also no doubt that most of these procedures, judiciously employed for chronic complaints, produce striking and grateful cures

During the past five to ten years, several surgical clinics have carefully analyzed their results following appendectomy, with the realization that

though there are still considerable differences of opinion, certain types are more clearly seen as potential poor results, and operation avoided. Poor results with persistence of symptoms, range from 10 to 70 per cent, frequently quoted as 30 to 40 per cent. There are several analyses, in which three to four years after 30 to 40 per cent of failures were reported following appendectomy, 10 per cent of failures are now reported

There is rather general agreement that two types of chronic appendicitis can be differentiated

1 Repeated painful attacks, usually starting with an acute attack. There are only one or two dissenters from the opinion that such patients should have appendectomy, and that this generally brings relief. Several state that if appendectomy were limited to cases in which repeated attacks with intervening free intervals were described, the operation, patient and surgeon would be much better off. "It is a wise rule never to diagnose chronic appendicitis and never to operate upon such a case without a history, definite or perhaps even indefinite, localized or with referred symptoms, which may be regarded as a probable attack of acute or subacute appendicitis", says Thomas R. Brown.⁵ This viewpoint is rapidly gaining adherents

Rolleston, Aschoff, Alvarez, and Seale Harris, have all stated that all chronic appendicitis cases have had previous attacks. Lichty³ makes no diagnosis of appendicitis unless there have been characteristic acute attacks

2 There is a second group, described alike by no two writers, in which most of the difficulty and confusion lie. This is made up of cases

of persistent right-sided pain with reflex gastro-intestinal symptoms of various forms

Crohn⁶ has described these cases under four groupings:

I Young adult men, in whom the distress simulates gastric or duodenal ulcer, probably due to pylorospasm. There is not the periodicity usually associated with ulcer, in these cases the distress is more irregular and intermittent, it comes long after meals, two to three hours, is usually located just above the umbilicus, and there are long free intervals

II Patients who have had obstinate constipation for years, with mild reflex gastric symptoms — heartburn, pyrosis soon after eating, halitosis, bad taste in the mouth, poor appetite. Sometimes there is no abdominal pain. Occasionally a case of this type will develop a sudden severe gangrenous appendicitis

III Indefinite and continuous low abdominal pain in the right lower quadrant, sometimes in the right hypochondrium. These cases simulate gallbladder disease, or occasionally new growth. When heartburn, belching and poor appetite occur in the neurotic, there is a natural tendency to make light of these symptoms

IV Unusual cases presenting chiefly diarrhea with no gastric symptoms. There may be severe upper abdominal cramps with nausea and vomiting, and no right lower quadrant tenderness

There is a good deal of difference as to operative indication in this group. Deaver insists that pylorospasm with distressing dyspepsia may be of appendiceal origin even if there is no right lower quadrant tenderness, and will be cured by appendectomy. Boas and Rehfuess, also, sometimes advise appendectomy for chronic abdominal complaints as a diagnostic procedure. If the symptoms are relieved, the diagnosis is correct. Most other recent writers dissent from this viewpoint,

and urge extreme caution in cases with no recurrent attacks

FAILURES

Perhaps most can be learned from analyses of failures. Several of these, from very careful follow-up services, have been reported recently

Whipple⁷ analyzed 53 failures making the following final diagnoses in these cases

Neuroses of various types	21
Visceroptosis	8
Colonic stasis—spastic	
descending colon	3
Tender cecum bound to adnexa	2
Tuberculous lymphadenitis	} 1 or 2 each
Cholecystitis	
Gastric ulcer	
Duodenal ulcer	
Sacro-iliac sprain	
Chronic colitis	
Pulmonary tuberculosis	

He cautioned against operating upon (a) those asthenic ptotic individuals belonging to the so-called carnivorous type with a long standing history of pain and tenderness in the right lower quadrant, and (b) those having many and exaggerated complaints, among them pain and tenderness in the right lower quadrant. These patients have neuroses of one kind or another and may be either the well nourished or the ptotic type

A similar list of 230 diagnoses in private patients who had had appendectomy without relief is given by Andresen⁴

Gastroduodenal ulcer	36 per cent
Gastritis and duodenitis	26 per cent
Gallbladder disease	35 per cent
Colitis	21 per cent
Pancreatitis	0.4 per cent
Adhesions	25 per cent
Hernia	7 per cent
Hemorrhoids	7.5 per cent
Carcinoma	3 per cent
Food allergy	7 per cent

Gibson's⁸ conclusions are frequently quoted and bear repetition. To avoid disappointment he advises

- 1 Comprehensive and detailed history taking
- 2 Careful physical examination
- 3 Excessive care before advising operation in women and all more mature individuals
- 4 Careful search at time of operation for other lesions
- 5 The sedulous avoidance of operations upon neurasthenics
- 6 Restrained, if there are no definite attacks or localized pain with nausea or vomiting
- 7 A good sized incision and a thorough exploration

Another study of end results, where 26 per cent of unsatisfactory results are recorded, ends as follows⁹

"The following points should be seriously considered in making a definite diagnosis of chronic appendicitis with a promise of permanent relief by operation

1 A complete detailed history of frank attacks. The nearer the history approaches the cardinal signs of appendicitis the better the prognosis for cure

2 Physical examination should be most thorough, ruling out especially genito-urinary and gynecological conditions and not overlooking lung pathology

3 Asthenic individuals, both male and female, with a suggestive neurotic make up should be subjected to long periods of observation with all refinements of diagnosis

4 Large incision

5 The finding of a diseased appendix is not enough to guarantee the patient complete relief

6 Delivering the appendix through a small incision and the use of dry sponges may favor the formation of adhesions"

Note the similarity in the conclusions arrived at in these two studies

Some of the facts brought out by these postoperative analyses of failures—and they all agree in substance—

are. Beware if there are no acute attacks. There are more failures in women than in men. There are more appendectomies performed for chronic appendicitis in women than in men, and the ratio should be more nearly the ratio of appendectomy for acute appendicitis in women and men respectively. Everyone who has analyzed his results urges one to beware of the neurasthenic, the neurotic, the long, thin viscerotropic persons of both sexes. They had best be left alone, or operated upon after very careful observation and exclusion of all other possible causes of abdominal pain and discomfort. One hospital reduced its failures from ten per cent to one per cent by first referring suspected chronic appendicitis cases to a psychiatrist.

DISCUSSION

From the above analyses, plus my own experience, the following generalizations can be made

Needless to say, chronic appendicitis should always be an exclusion diagnosis. Certain types and age groups are more apt to have chronic appendicitis. All analyses have shown that complicating conditions—ulcer, gallbladder disease, ureteral and kidney conditions, etc.—are more frequent the older the patient. In children, the attacks may be milder, and are more frequently overlooked. The tenderness and pain may be located higher, at the level of the umbilicus, because the cecum frequently lies higher. There is not the confusion of diagnosis which ulcer, gallbladder disease, salpingitis, etc., bring in later life, but there is more apt to be abdominal pain referred from pulmonary or upper respiratory infection than in adults. In-

cidentally, the incidence of acute appendicitis is higher in epidemics of upper respiratory infections than at other times. Personally, I am more apt to believe a child when he complains of transient, but repeated bellyache than an adult, and think these cases usually are appendicitis. If in doubt I tell the mother that the child probably has appendicitis, should be watched carefully, and taken care of at the first recurrence of trouble. I have removed some surprisingly involved appendices in children after mild attacks, and do not recall as many postoperative failures as in adults. A normal child should not know he has a "stomach", and repeated unexplained "bellyaches" can be considered more significant in children than in adults.

URETERAL CALCULUS

Ureteral calculus is not hard to avoid if one is on guard. None of the postoperative analyses record more than two or three cases which subsequently proved to be urinary calculi. A calculus in a young adult usually gives a severely painful seizure, with the pain out of all proportion to the local findings. The cases I have had the most difficulty with have been between 35 and 50 years of age, generally heavy set men, with a dull right-sided ache. A few white blood cells may be all the urinary findings given by a large kidney stone. When there is the slightest doubt, I look at the sediment myself.

GALLBLADDER DISEASE

The gallbladder is coming to the fore as the chief rival of the appendix. Disease of this organ is now one of the most frequent affections for which

laparotomy is undertaken. It is being diagnosed earlier in life than formerly, and since the Graham-Cole test (which has a high degree of accuracy), is being found more frequently.

Graham believed that the majority of cases in which symptoms were thought to be due to chronic appendicitis are due to gallbladder disease and spastic constipation. Indeed, Jordan and Lahey¹⁰ recommended that if certain abdominal symptoms — gas, distress, and more or less atypical pain — do not respond to rest in bed, bland diet, etc., cholecystectomy is sometimes indicated, even if the gall bladder fills well with the dye. I have had one such case in a heavy set man, whom appendectomy failed to relieve of mild but persistent dyspepsia. The gallbladder filled well, was grossly normal on removal, but microscopically showed chronic inflammation of moderate degree. The patient has remained free of abdominal distress he had had for years. Irland¹¹ goes one step further and feels that the gallbladder may be frequently responsible for symptoms which in no way implicate the digestive tract, the gallbladder acting as a silent focus of infection.

This important rôle of the gallbladder has been stressed only for the past few years. Perhaps some of the poor results in patients classed as neurasthenics have this explanation.

SPASTIC CONSTIPATION AND ALLERGY

Students of diseases of the colon feel that this organ is more frequently deranged than is the stomach "although the stomach has had more advertising." Its most common malfunction is a condition of localized spasm, caused by undue muscular tonus which, in turn,

probably results from abnormal nervous stimuli—imbalance of the sympathetic nervous plexuses governing the colon Duke, Vaughan, Rowe¹² and others feel that these manifestations are allergic in nature and due to food sensitization Cramps and flatulence are produced, and similar heightened neurogenic secretory stimuli produce mucous diarrhea These localized spasms can occur throughout its extent, but are more common in the descending colon When prolonged, intestinal stasis is produced proximalward, which may easily result in secondary dilatation and tenderness in the cecum, the rolling, gas-filled cecum which was thought significant of chronic appendicitis Kantor¹³ feels that the position of the cecum is important clinically If it is high-lying, there are few symptoms If low-lying, symptoms are common, the drag of the colon on adjacent organs (possibly the duodenum) perhaps being responsible

Eggleston¹⁴ reported that 22 per cent of 100 spastic colon cases had had appendectomy without relief These individuals, preponderantly women, long, thin, viscerotonic, with cold extremities, low blood pressure, easily fatigued, "belly conscious", are avoided by all who know Their dyspepsia, flatulence, cramps, and diarrhea are expressions of motor and secretory dysfunction of the colon due either to sympathetic nervous system imbalance, or perhaps localized allergic spasm and edema, and are not to be explained upon an anatomical basis such as appendectomy might cure

Another pitfall which has been recognized recently is abdominal allergy—abdominal pains due to food sensitivity Osler¹⁵ wrote an article in

1904, "On the surgical importance of visceral crises in the erythema group of skin diseases", cautioning against the danger of unnecessary surgery Since then, the old fashioned angio-neurotic edema, or urticaria, modernly conceived as the characteristic lesion of allergy, is made to explain a host of apparently unrelated phenomena Muscular spasm and mucosal congestion and edema, the pathological changes in allergy, can occur anywhere in the body In the brain, they are said to produce cerebral edema for which decompressions or fifth nerve injections have been done In the alimentary canal, canker sores, coated tongue, ulcer-like pains, gastro-intestinal bleeding, pruritus and have all been ascribed to local sensitization of various parts of the alimentary mucous membrane¹² The liver cells and gallbladder mucosa becoming edematous, cause right hypochondriac pain for which gallbladders have been removed Urinary symptoms (dysuria, frequency, etc.), some forms of hypertension, hypotension, disturbed menstruation, are all described as due to sensitization to certain foods or other articles A localized spasm of the Fallopian tube has been reported as simulating ectopic pregnancy, the sting of *Pediculus pubis*, or of the bed bug is presumably due to a localized allergy from the toxins excreted

Seriously, however, food allergy may cause various atypical abdominal symptoms, pains, colics, distress, distention, nausea, pyrosis, vomiting, spastic constipation, diarrhea and colitis The pains are more often generalized and in the lower abdomen Appendectomy has been performed frequently when the pains could have

been cured by elimination of certain foods, generally wheat, milk or eggs. More important still, distress continues until the offending factor is sought out and eliminated

The following case history demonstrates the confusing picture which abdominal allergic manifestations may present.

S M was a boy, aged 13 years. On his first visit to the clinic in June, 1929, it was noted that he had had two attacks of pain in the right lower quadrant, each of two weeks' duration. During the attacks, pain came two or three times daily, with no relation to food. Flexing the right thigh and lying down stopped the pain. There was slight tenderness over McBurney's point, and the x-ray diagnosis was disease of the appendix.

He returned on April 12, 1930, having recently had another attack, this time with the pain confined chiefly to the epigastrium. Because of marked dermographia he was referred to the allergy clinic (Dr Geo L. Waldbott) for study. It was found that he had had eczema; his father and one sister also had had eczema. There was no other positive finding except an eosinophilia of seven per cent. He was sensitive to cheese, wheat, beef, asparagus, rabbit hair, eggs, and chicken feathers. Under treatment by means of elimination of these articles aided by injection of their extracts the child did very well until the ragweed season started, when there was vomiting, abdominal pains, upper respiratory catarrh and exacerbation of the eczema. On one occasion, injections of ragweed produced severe pain in the abdomen. There has been occasional slight recurrence of pains and sensitiveness, but the boy had gained 15 pounds and was much improved when last seen in March, 1931.

One must be careful here. I have seen attacks recur after the patient was supposedly cured by treatment directed against food allergy, necessitating appendectomy.

OTHER CONDITIONS

It is well to remember also that sacro-iliac disease causes anterior abdom-

inal tenderness. (Baci's point). A three-eighths inch lift on the right heel has corrected a lumbar lordosis for which three operations on the abdomen had been done. Tuberculosis and cancer of the cecum are frequently indistinguishable from chronic appendicitis.

As noted, many writers state that unless there is tenderness in the right lower quadrant no operation should be undertaken. I have had three patients in whom there was no right lower quadrant tenderness and in whom definite chronic appendicitis was found.

The rare or unusual case of appendicitis can simulate almost any intra-abdominal disease—depending chiefly upon its position. Ewald¹⁵ in 1899 introduced the term "appendicitis larvata" to describe cases where "the pain of which the patient complains, leads him and the doctor in the first instance to anything but an illness originating in connection with the appendix." Pain under the left costal margin, at the right costal margin (appendix lying underneath the liver), or behind the kidney, may be the only symptom of appendicitis. An appendix plastered in the pelvis, or wrapped about the sigmoid or rectum may give diarrhea, vomiting, loss of weight, mass, etc., exactly simulating carcinoma.¹⁶ Underneath all the coils of intestine, it may simulate mild subacute obstruction. Hematemesis and hematuria can be caused by chronic appendicitis.

X-RAY DIAGNOSIS

A battle royal has raged concerning the value of X-ray examination in chronic appendicitis. Filling, non-filling, segmentation, delayed emptying, tenderness over the appendix, etc., all have proponents and opponents. An

important practical consideration frequently concerns whether a patient of moderate means should be subjected to the (for him, considerable) expense of an X-ray examination. The late Dr. Carman of the Mayo Clinic was rather disdainful of the diagnostic value of the X-ray in appendicitis, and this was well known.

Deaver expressed himself rather forcefully.¹⁷

"It is my experience that if a careful study of the history with painstaking physical examination does not make the diagnosis it will usually not be made by the roentgen ray study.

"Cholecystography and roentgen ray examination have not given me so much satisfaction in differentiating between the chronic gallbladder and the chronic appendix as have a carefully taken history and a carefully conducted physical examination."

One internist states that the main cause of needless appendectomies is the "furor operandi" of ambitious surgeons, whose chief aid and abettor is the roentgenologist. Rehfuess blamed the disinterested surgeon and said he never saw a surgeon fluoroscope a patient, and a surgeon was no more competent to pass upon X-ray evidence than a roentgenologist was to remove the appendix.

As with everything, there is a middle course. Lahey's opinion was "Expertly applied, wisely interpreted and properly correlated no one can question its (roentgenological examination of the appendix) inestimable value."¹⁸

Merritt and Moore¹⁹ very recently have stated that "by many, this subject (X-ray examination of the appendix) has been unheeded, and the method has failed, we believe, to receive the consideration that it merits."

The X-ray examination is sometimes more informative than other examinations, as in the following case.

Mrs. N. P., aged 42 years, was first seen August 11, 1930, complaining of "indigestion" and gas on the stomach. For several months she had had occasional spells of indigestion. During the past two months, she had had three attacks of more generalized abdominal pain, lasting two to three days, accompanied by watery diarrhea. The pain was more on the left than the right side of the abdomen. There was no constipation. She had been on ulcer regime for five weeks. She had been in the country during the summer and there was some question about the well water used, several people having had diarrhea.

Examination revealed a pale, frail, ptotic woman, negative except for some general soreness over the left side of the abdomen, none elsewhere. X-ray (Drs. Evans and Reynolds) showed a long pelvic appendix which was tender, and retained barium 72 hours even though the cecum was empty.

Because the clinical picture was not clear, she was observed further. After one or two more general abdominal pain attacks, she developed a typical attack with pain in the upper abdomen shortly followed by soreness and acute tenderness in the right lower quadrant.

Operation revealed a long appendix, the midportion dilated by two moderate sized concretions, the tip thickened and sclerotic. She has remained well since the operation.

A roentgen examination which shows a tender, fixed appendix, is very helpful diagnostically. Tenderness moving with shifting of the appendix, is also diagnostic. A persistent kink representing adhesions at that site, or adhesions about the terminal ileum means disease in a high proportion of cases. If abdominal palpation elsewhere causes pain over the appendix, or pressure over the visualized appendix causes pain in other parts of the abdomen, this is significant.

On the other hand, "beading", seg-

mentation of the lumen, and incompetency of the ileocecal valve, are found frequently in normal persons. Stasis and delayed emptying certainly are not of as much importance as originally considered. Moore and Merritt¹⁹ do not mention any of these as X-ray signs of appendicitis. Kantor,¹³ from extensive X-ray and clinical studies of these cases, found that cecal stasis was even more common after appendectomy for chronic appendicitis than before operation, (27 per cent unoperated, 29 per cent appendectomized individuals) and adds facetiously that if the appendix were not removed, "there would be more stasis in it after operation than before" *

Unquestionably the chief usefulness of the gastro-intestinal series in these cases lies in excluding ulcer, gallbladder disease, and diseases of the colon, not forgetting the diagnostic aid of the flat kidney plate, and the help that establishing the anatomical position of the appendix gives in certain cases. Ulcer and appendicitis sometimes exist together. Deaver speaks of this. I do not think the incidence is as high as some have stated, maybe five to ten per cent would be correct. As mentioned above, several who have written on the subject feel that there is no upper abdominal dyspepsia which is cured by appendectomy. However, if the X-ray shows an irritable stomach, without ulcer, and a tender appendix, that, I think, is confirmatory evidence of appendicitis. But, after this is said my experience corresponds to the trend of recent opinion, there is a gradual rebirth or renaissance of the idea that a half hour's questioning, perhaps re-

peated two to three times, plus careful abdominal palpation is more valuable to the patient than most of the expensive tests. The follow-up studies generally note this. In their conclusions as to how to avoid unsatisfactory results, there is little mention of X-ray examinations, but all stress careful pre-operative history and examination, and knowledge of which types to avoid.

OPERATION

A word about the operation. There is a general feeling that it is devoid of mortality and complications, but there is a recorded mortality of 1.5 to 2 per cent in very good hospitals. I have never used a McBurney incision. Gibson,⁸ after his first analysis of failures in 1920, gave up the McBurney and uses entirely a large rectus incision, for exploration. However, a wide operative exploration is not a panacea for right-sided abdominal pain. In 73 of 102 cases it did not avert an unsatisfactory result.

Concerning the appearance of the appendix at operation, there is no doubt but that partial or irregular or complete obliteration of the lumen indicates a chronic process and relief will follow operation. Fecaliths are plugs of intestinal contents which have become stagnant in the appendix lumen and become inspissated, encrusted with mucous, lime salts, etc. Their presence is presumptive assurance of a good result. The doubtful types are where one finds only slight congestion, a dulling of the normal lustre of the serosal surface, or coiling or slight kinking of the appendix—appearances which one frequently sees when operating for disease of other intra-abdominal organs,

*Personal communication

and which seem like rather meager pathological changes upon which to explain all the patient's symptoms and to be the *picce de resistance* of all the study, trouble, and expense the patient and doctor have gone through

There is controversy here. Some deny that these slight findings represent chronic appendicitis. The truth is that the border line between pathological and physiological change in the appendix probably has not been defined, and that, as stated above, the only proof in many cases is that, having followed these patients and found them free from pain after operation, they probably had appendicitis. In other words, the preoperative examination may be more accurate than the findings at operation.

END RESULTS

I have summarized 50 of my own personal records of patients upon whom appendectomies had been done for chronic appendicitis in whom I knew the end results, followed three to six months later. All acute appendicitis cases were excluded. All these cases had had long continued pains, had normal temperature and normal blood count. There were no fatalities, and no postoperative complications. Thirty-seven cases had had previous attacks of right lower quadrant pain, with approximate freedom from pain between attacks and no other symptoms. As near as I know all of these were relieved. I either have a note that the patient was well or free from symptoms three to six months later, or a note from the attending physician that such was the case.

Of the remaining 13, there were four cases where there had been epi-

gastric distress associated with right lower quadrant attacks. One of these cases had an X-ray diagnosis of prepyloric and duodenal ulcer. All of these patients are cured following appendectomy.

Another case developed heartburn shortly after appendectomy (definite appendicitis was found at operation). Her pains in the right side have ceased, but she still has occasional heartburn relieved by alkalis. Two cases had only epigastric pain—no right lower quadrant symptoms, but examination revealed tenderness there. They were cured. Two cases had persistent right lower quadrant pain with no definite acute attacks. They are relieved. Three cases are unrelieved. One may have a chronic cholecystitis, the other two probably belong to the irritable colon group.

In one case, I made a frank error. This patient was vomiting, had abdominal pain, and also complained of deafness in the right ear, which I told her she could have attended to later. This deafness and the vomiting were due to central nervous system lues affecting the internal ear mechanism. It cleared up after antiluetic therapy.

Thus 75 per cent of the group had repeated attacks of right lower quadrant pain only, and all were cured. In the remaining group several were relieved of epigastric distress by appendectomy, and there is an occasional operation for persistent right sided pain or persistent epigastric distress, with good results. All of the four failures are found among these more atypical cases.

The age group as a whole is young: 2 over 40, 6 between 30 and 40, 17 between 20 and 30, 15 between 10 and

20. There are apparently no examples of chronic appendicitis in this series under 10 years of age. Although chronic appendicitis does occur in young children, most children under 10 years have acute appendicitis or a recurring acute attack. Incidentally, during the period of this series, there was one case in which operation was advised against, and the patient subsequently was completely relieved by appendectomy done elsewhere, also two cases in which operation was refused and the patients have remained well.

The series is not large, perhaps all subsequent histories and later developments are not completely known and perhaps some patients might have gotten well without operation. However, the review of these cases leaves the reiterated impression. It is time well spent when chronic appendicitis is suspected to examine a patient two or three times for one-half hour each time before deciding to do an operation. In this examination, the interpretation of the clinical history is the most important single factor in avoiding poor results.

Clinical Teaching with Special Reference to Bedside Study of Disease*†

By L. J. MOORMAN, M D, F A C P,
Oklahoma City, Oklahoma

THE word "clinical" means to lie in bed. Clinical medicine in its broadest sense means that part of medicine which has to do with the bedside investigation of disease in the living body. Clinical medicine is not a school of dogma, it is a school of method. Progress in clinical medicine is not hedged about by fixed limits, but may go as far as the individual's methods of observation and investigation can carry him.

The medical student should be impressed with this fact early in the course of his studies, because there can be no better preparation of the soil for the growth of observation, or for the budding and flowering of genius than the knowledge of an open course where all who enter the race are equally free and independent in the development of their talents.

In the middle of the sixteenth century Montanus first taught medicine by bedside instruction at Padua. He was contemporary with Vesalius, who was at this time preparing the *Fabrica* for publication, laying the foundation for modern anatomy, and giving it a place

in the curriculum which it has never lost. We may safely say that clinical teaching dates from this period at Padua, but there was little progress during a period of three hundred years.

The awakening which came in the first part of the nineteenth century ultimately placed medicine on a broad basis. Lavoisier became one of the prime movers through his discovery of the nature of respiration and the sources of animal heat. The movement gathered impetus through the enthusiastic studies in gross pathology, carried on in France by Bichat and his followers, and in Vienna by Rokitsansky and Skoda. Also through the development of percussion and auscultation by Corvisart, Laennec, Bayle, Piorry, Louis, and Andral.

While some mistakes were made and false conclusions drawn, the study of pathological anatomy and the more intelligent use of percussion and auscultation put clinical medicine forward with a bound. This was particularly true with reference to diseases of the heart and lungs. Wherever possible the symptomatic classification of disease gave place to the anatomic classification. Through these methods bedside study and observation received a great stimulus and there soon came a

*Received for publication, November 7, 1931.

†From the Department of Clinical Medicine, University of Oklahoma.

better understanding of many diseases. Laennec made his significant contributions to our knowledge of diseases of the heart and lungs; Louis through his clinical and anatomical study of disease, and his statistical and analytical methods not only made valuable additions to our knowledge, but he exerted a remarkable influence on the teaching of clinical medicine. It might be said that modern clinical teaching in America had its origin in the young American students of Louis during the fourth decade of the nineteenth century. Among these were Jackson, Shattuck, Holmes, Gerhard, Stille, Power, Flint, Swett, and Clark

With the growth of clinical medicine have come all the influences of physiology, bacteriology, physiological chemistry and the various laboratory and mechanical aids to diagnosis, all designed to supplement clinical diagnosis, yet many of them serving as a dangerous lure for the unwary student of bedside medicine. He is often tempted to think of this or that test or device as a short-cut, rather than an aid to diagnosis or a method of confirming clinical findings, and may make the fatal mistake of slighting the history of the case and omitting or abbreviating the bedside study while he awaits the laboratory report. When the report is received, it may be given unwarranted weight, because there is nothing in the scale with which its value may be checked.

The bedside study of a case should begin with a carefully taken history and should not end until every organ in the body has been thoroughly examined. The true spirit of the faithful observer is expressed in the following

quotation from Louis' *Researches on Phthisis*.

"All these cases were taken on the same principles and with the same details; and as it appeared to me impossible to carry on a system of observation such as this and attend to private practice at one and the same time, I relinquished the latter altogether for the time being. I regularly passed three or four, and sometimes five hours daily in the hospital, devoting at least two hours to each postmortem examination. And although habit must have familiarized me with anatomical investigation, I still employ the same time I did two years ago in the examination. For I am convinced that if we wish to observe well, we must not observe hastily, and that the sole means of rectifying unfavorable errors is repeatedly to submit to new examination, questions which we may have at one time believed settled, and consequently to go on perpetually observing the same objects, just as if they were, in each instance, beheld for the first time."

William Harvey also possessed the spirit which should animate the true clinician when he said

"Let us then blush, in this so ample and so wonderful field of nature to credit other men's traditions only. *Nature* herself must be our adviser, the path she walks must be our walk, for so while we confer with our own eyes, and take our rise from meaner things to higher, we shall at length be received into her closest secrets."

The teacher of clinical medicine today carries a heavy responsibility. The "primal sympathy of man for man" which gave origin to medicine is being threatened by the various distracting diagnostic and therapeutic agencies, which, through spectacular appeal, or the promise of a short-cut, tend to draw the student away from the bedside.

While our knowledge of disease and its treatment has been greatly aug-

mented in the past century, and while this increased knowledge has materially altered our diagnostic methods and our therapeutic procedures, it has in no way altered the relation of host and disease. Human nature is just the same: disease untreated, works the same ravages in the human organism. The need of sympathetic understanding is still eminent. The clinical teacher must cultivate the *art* of medicine, his manner must be such as to inspire confidence and hope, and yet "the seeing eye, the hearing ear, the sensitive fingers and the understanding mind" must be employed with such searching effect that they approach the accuracy of a science. With these qualifications the teacher of clinical medicine should stand in relation to the student as a guide at the threshold of this most intricate and interesting unit of society, the human organism, ready to acquaint him with the normal living anatomy and physiology, prepared to elicit the history of disease, ready to demonstrate the methods of physical exploration for the purpose of discovering departures from the normal, quick to sense mental and psychological deviations, trained in the correlation and diagnostic appraisal of facts obtained; generous but discriminating in the use of laboratory and mechanical aids, and finally conservative and humane in the application of treatment. I think this is not too much to ask of the clinical teacher, the more he brings to the bedside, the more he will take away.

The student can be interested in the methodical demonstration of the normal and the discovery of departures from the normal. It is a mistake to

allow him to go through medical school with the impression that if he learns anatomy, physiology, biological chemistry and bacteriology he will then be suddenly endowed with so-called diagnostic instinct, or as Oliver Wendell Holmes says "intuitive sagacity". He must learn that intuitive sagacity is synonymous with hard discipline and that every individual is endowed with special senses which if properly trained, may become powerful instruments of precision, incredibly keen and penetrating in their search of knowledge, and to go on the trail of disease with such weapons is like playing an interesting game.

Doctor Henry A. Christian has said

"Perhaps the fault of the student is, more than we admit, a reflected fault of the teacher. We are constantly criticized through our students' work by their plunging immediately into instrumental and laboratory methods of examination of patients. Is not that the thing that we are doing ourselves a great deal more than we should, if we remember that we stand before our students as exemplars? Are we not too much inclined to fail to commit ourselves definitely to a certain finding as normal or abnormal after simple methods of examination? I am very sure that I am guilty often in that respect, notwithstanding that I rather carry it on my conscience to be guiltless as far as possible. As teachers we refer too readily to the x-ray or examinations of that special sort. I do not mean at all to decry reference to the x-ray, but we refer the patient for special examinations before we commit ourselves in the presence of the students to our judgment about the matter based on history and simple methods of examination. It seems to me we need to go over our patients with our students, using simple methods of examination, as soon as they come into the clinic or into the hospital, put down what we find, draw a conclusion, and then let other methods check up. It is not necessary, then, to argue with the student either the

merits or the limitations of the simple method. You are shown to be correct or incorrect, and in time the student will learn both your ability to use simple methods of examination and your failures in so far as your limitations are set by these other methods."

With these facts in view it would seem wise for medical school curricula to offer more bedside instruction and

less amphitheater surgery. May the spirit of such men as Sydenham, Boerhaave, Laennec, Allbutt, and Osler inhabit the wards of every teaching hospital in order that the simple methods of bedside investigation may be preserved and that the knowledge of clinical medicine may reach its ultimate refinement!

Wastage of Health and Money in Sectarian Cults

"THE objection to the existence of sectarians is not so much that their therapeutic methods are in themselves incorrect as that the use of these or any other therapeutic measures by individuals untrained in the medical sciences, unable to diagnose disease, and unaware of their own limitations, is unsound, dangerous, and economically wasteful. It is established beyond doubt that in some disease conditions cures may be effected through the prompt employment of the appropriate remedial measures—early surgical intervention for cancer and acute appendicitis, antitoxin for diphtheria, quinine for malaria, salvarsan for syphilis, etc. Delay in the diagnosis of these conditions and in the employment of the proper remedy may result in a more serious illness than might otherwise occur, or may even result in death. There is danger not only to the individual but also to the community. How foolish it is for a community to maintain an elaborate public health machinery to prevent the spread of certain communicable diseases, and yet permit individuals to practice who are unable to differentiate diphtheria from pneumonia or scarlet fever from measles. In experimenting with sectarians, people often spend large amounts of money which they can ill afford."

From *The Healing Cults—A Study of Sectarian Medical Practice Its Extent, and Control*. By LOUIS S. REED, PH.D. The Committee on the Costs of Medical Care, 910 Seventeenth Street, N.W., Washington, D.C.

Editorials

DEATH FOLLOWING THE USE OF ACETYSALICYLIC ACID IN ASTHMATIC CONDI- TIONS

Notwithstanding the growing literature with constantly multiplying reports which detail serious untoward effects and even death following the use of acetylsalicylic acid in attempting to obtain relief from asthmatic conditions, further emphasis of this danger is indicated. An illustrative case is to be found in this issue of the *ANNALS*. In Case I of the group of patients described by Dr Macdonald¹ it had been noted on several occasions that severe attacks of asthma had followed the administration of coal-tar products. Finally, one-half hour after taking 10 grains (0.6 gm) of aspirin, the patient suffered a severe attack of asthma in the course of which death occurred. In discussing the etiology of this condition, Macdonald gives a brief review of earlier reports of similar fatalities, and calls attention to the fact that it is altogether out of the question to attribute the fatal outcome under such circumstances to the toxicity of acetylsalicylic acid in the ordinary sense of the term. He quotes de Jankovich on this point to the effect that the lethal dose can be fixed at 20 gms. The ill-effects which have been observed following the ingestion of but 5 or 10 grains (0.3 to 0.6 gm) must have an allergic basis.

A recent coroner's case in the experience of the writer apparently falls in this group. A robust-appearing young man consulted a druggist for symptoms which he believed indicated a "cold". He was given two remedies of which one was acetylsalicylic acid in 5 gr tablets. He took two of these tablets before leaving the store. Whether he took others is not known. Several hours later he was found in bed extremely dyspneic and cyanotic, and died before a physician could be obtained. Attention is called also to the recent paper by Lamson and Thomas² describing four examples of allergic response, one fatal, following the use of a nostrum for the treatment of asthma, the chief ingredients of which are acetylsalicylic acid and caffeine. The frequency of such ill-effects might lead to the impression that in some way a synergistic effect exists between the asthmatic state and acetylsalicylic acid. Rather must we recognize the pathologic constitution (thymico-lymphatic) which is the common substrate for the allergic response in both instances.

It is indeed with truth that Walzer³

¹MACDONALD, I. G. The local and constitutional pathology of bronchial asthma, *ANN INT MED*, 1932, vi, 253-277.

wrote "Aspirin and the closely related coal-tar products are among the most treacherous drugs employed in the therapy of asthma. Their routine or careless prescription for atopic patients is a dangerous practice."

CARDIAC HISTOPATHOLOGY IN THYROTOXICOSIS AND ADENOMATOUS GOITER

Whether there are characteristic histopathological changes, or any changes at all for that matter, in the hearts of patients who have shown clinical evidences of cardiac disturbances in association with thyrotoxicosis has been subject to much difference of opinion. The staff of the Department of Pathology has recently conducted a purely objective investigation of this problem, a preliminary report of the results of which is to appear in a forthcoming number of the *American Heart Journal*. In connection with other lines of investigation which are described in that report, from a total of 43 autopsies of cases of exophthalmic goiter, 35 were selected as being free from evidences of syphilis, rheumatic fever, infective endocarditis or severe coronary atherosclerosis so that as far as possible known causes of myocardial changes were eliminated. A control series was then set up by matching each individual case of the exophthalmic series with another of the same age and sex, i.e., with a case as similar as possible in all respects except that exophthalmic goiter had not been present. Comparable microscopical slides from the hearts of these 70 cases were then examined and the results tabulated as to thirteen items commonly made note of in such examinations of the heart wall. In compar-

ing the two series by this method only four features were found to occur with sufficiently greater frequency in the exophthalmic series to suggest that they might be significant. These were myocardial hypoplasia, fibrosis of the myocardium, endocardial sclerosis and cellular infiltrations. Myocardial hypoplasia was judged largely by the state of the muscle of the right ventricle. Its significance is that of constitutional pathology, vascular hypoplasia being a constant finding in the Graves' constitution.

Of the hearts in the exophthalmic series, 80 per cent showed myocardial fibrosis as compared with 51.5 per cent in the control series. The areas of fibrosis were usually small and were found chiefly in the left ventricular wall and the papillary muscles. The type of the fibrosis was such that it could not have been due to arteriolar occlusion. In four instances cellular infiltrations associated with patchy fibrosis were found, but in none of these were early lesions of the muscle fibers themselves seen, and the wandering cells were relatively few. In one case only was there a severe active myocarditis of the type described by Fahr. In this heart there were many focal lesions occurring throughout the myocardium, even in the auricles. These lesions were non-purulent and were present in all stages of a series extending from focal necroses with lymphocyte and plasma cell infiltrations to old and somewhat hyaline patches of fibrosis. As far as histopathological study could determine, such changes as were present in this heart would be entirely capable of leading to the areas of fibrosis found in a large proportion of the

exophthalmic series If such was their etiology, it is difficult to understand why, in such a relatively large series, only a single example should be found in a stage of noteworthy activity Nevertheless, no other etiological factor than the hyperthyroid state could be found for that particular case

The hearts of 55 cases of adenomatous and nodular colloid goiter were compared by the same method with a matched control series from non-goitrous individuals No significant difference in the incidence of pathological changes could be discovered between the two series

Abstracts

Über das Auftreten von Perikarditis nach Lungeninfarkten [The Occurrence of Pericarditis Following Pulmonary Infarction] By PAUL WERMER (Klin Wochenschrift, 1932, xi, 329-330)

The deplorable frequency of both spontaneous and post-operative venous thrombosis and pulmonary embolism in recent years has directed attention to the etiology and pathogenesis of pulmonary infarction, and justifies description of a clinical picture which the author believes has not previously been detailed—pericarditis resulting from infarction of the lung The etiology of this condition is considered to be direct extension of the fibrinous pleuritis which is always found over the base of an infarct to the pleuropericardial layer (pericarditis externa) and then to the visceral pericardium Characteristic cases are presented In making the diagnosis the evidences of the initial pulmonary pathology will usually be clearcut The sudden appearance of stabbing pain in the side, cough and dyspnea, after an operative procedure, together with evidences of collapse, pallor or cyanosis, tachycardia, and thin feeble pulse make the diagnosis of embolism of a small pulmonary artery extremely evident To this picture the evidences of a pericarditis are added in the syndrome under consideration Pericarditis having this etiology was characterized in the author's cases by the roughness of the friction sound, by its fugacity and by the severe pain in the cardiac region which was readily distinguishable from the

pain produced directly by the infarct Differential diagnosis between this and other forms of pericarditis is discussed Since pulmonary infarction at times gives no clinical signs or symptoms, in the association of the two conditions here described may be found the cause of some examples of "idiopathic" pericarditis for which no explanation has hitherto been available

The Amount of Epinephrin in Extracts of the Medulla, Cortex and Whole Suprarenal Gland of Rabbits, Pigs, Cattle, and Horses By TAKEO KOZIMA, MAMORU NEMOTO, SHIZUKA SAITO, HIROSHI SATO, and TAISUKE SUZUKI (The Tohoku Jr of Exper Med, Sendai, Japan, 1932, xix, 205-232)

Extracts were made from the medulla, cortex and whole substance of suprarenal glands of oxen and horses, of the medulla and whole glands of pigs, and of the whole gland of rabbits The epinephrin content of these extracts was estimated by means of the colorimetric method of Folin, Cannon and Denis, that of Suto, the rabbit intestine segment method, the blood pressure of the pithed dog, the cat paradoxical pupil reaction, the perfusion of toads' legs and rabbits' ears The results obtained are presented in tabular form The suprarenal gland of the horse gave similar values for epinephrin regardless of the methods applied, but the glands of rabbits, pigs and cattle gave variable results in respect to the methods used, and the character of these

variations differed with the various species as well. To explain these variations, which are confidently believed not to depend upon technical error, certain suggestions are made. It is possible that the active principles in the extracts should not be assumed to be adrenalin alone, but some mixture of adrenalin and allied substances. Or, extracts may contain besides adrenalin some substances which act to intensify the action of epinephrin in various degrees according to the test object employed. Perhaps both of these alternatives act together. As previously recorded, there was demonstrated in small amount in the adrenal cortex of cattle and horses that substance which gives a positive reaction to the Folin test but none to the Suto test or to the biological tests.

Observations on Heart Sounds with Particular Reference to Gallop Rhythm and Sounds of Auricular Origin By A. GARRARD MACLEOD, FRANK N. WILSON and PAUL S. BARKER (Proc Soc Exp Biol and Med, 1932, xxix, 1009-1010.)

Two Einthoven galvanometers coupled in tandem were used to record the electrocardiogram and the heart sounds simultaneously, and the electrical stethoscope manufactured by the Western Electric Company was used to convert the sounds into electrical variations. The study of a large number of phonocardiograms led to the following tentative conclusions. From the graphic standpoint gallop rhythm may be defined as a condition in which three sounds occur during each cardiac cycle. Several varieties may be distinguished: (a) Protodiastolic gallop rhythm in which the extra sound follows the second heart sound by a constant interval and occupies the same position in the cardiac cycle as the normal third heart sound. (b) Presystolic gallop rhythm in which the extra sound precedes the first heart sound by a constant interval,

and is almost certainly of auricular origin. The onset of the extra sound falls within the P-R interval of the electrocardiogram. This appears to be the most common type of gallop rhythm. It is particularly frequent in cases of arterial hypertension. (c) Systolic gallop rhythm in which the extra sound falls within the limits of ventricular systole. This type of gallop rhythm is uncommon and apparently has no clinical significance. (d) Gallop rhythm due to audible auricular sounds when the P-R interval of the electrocardiogram is increased beyond normal limits in which case the extra sound may fall in any part of diastole. This should probably be considered a variety of presystolic gallop rhythm.

Production of Thyroid Hyperplasia in Rats and Mice by Administration of Methyl Cyanide By A. W. SPENCE and DAVID MARINE (Proc Soc Exp Biol and Med, 1932, xxix, 967-968.)

The senior author and his associates have shown previously that the daily subcutaneous administration of small doses of aliphatic cyanides to young rabbits of either sex, maintained on a diet of alfalfa hay and oats, will produce thyroid hyperplasia within 21 days. Methyl cyanide was found to be most potent in this respect. Rats were given daily subcutaneous injections of varying doses of methyl cyanide in water. After 21 days only very slight thyroid hyperemia was shown. After 28 days there was definite thyroid hypertrophy, but it was obvious that the thyroid of the rat was less reactive than that of the rabbit. With increased dosage for the intervening days the thyroids were larger and more hyperemic at the end of 36 days. Although there were individual variations, in general the thyroid reaction was proportional to the dosage. Only a slight thyroid reaction was produced in mice after periods of dosage of from 11 to 34 days.

Reviews

Surgery of the Chest By GEORGE F STRAUB, M D, F A C S xx + 475 pages, 341 illustrations, including 68 in color Charles C Thomas, Springfield, Illinois 1932 Price, \$10 50 postpaid

Although outside of the field of practice of most of the readers of the ANNALS, it is appropriate to give brief mention to this book. There is perhaps no other anatomical area for specialization in which community of knowledge is more essential on the part of the internist and surgeon than the thorax. Since this book presents the recent advances in this field and discusses the application of surgical methods to a considerable number of diseases usually first seen by the internist, this treatise must be of interest and value to that group. For the surgeon it describes technical procedures as well. Not only is this book well written but it gains much from its numerous illustrations, many of which are reproduced from drawings by the author. Skillful use has been made of an additional color in many of the figures. The format is excellent.

Lang's German-English Dictionary of Terms Used in Medicine and the Allied Sciences with their Pronunciation Revised and edited by MILTON K MYERS, M D, Neurologist to the Northern Liberties Hospital, Chief of Nerve Clinic, St Agnes Hospital, Consulting Neurologist, Jewish Hospital, Philadelphia, etc. Fourth edition, enlarged 926 pages P Blakiston's Son and Company, Philadelphia Price, \$10 00

Practically every English-speaking reader of medical German, not born to the language, has made use of the earlier editions of Lang's German-English Dictionary of medical terms. Such a dictionary is, in fact, indispensable. The standard German-English dictionaries lack all except the more frequently used medical terms and cannot

give the specific medical significance of many terms which have a common usage as well. This new edition has been entirely reset. This was made necessary by the addition of the pronunciation, in easily understood English syllables, of each word. Also 3,500 new words have been added, bringing the total to approximately 56,500 definitions. This gives a work which is not only satisfactory for the general reader of medical German but also an important aid to the translator or researcher. This new edition will be welcomed by the users of its predecessors. German remains the most important foreign language for the English-speaking physician.

Biochemistry in Internal Medicine By MAX TRUMPER, Ph D, Clinical Chemist and Toxicologist, formerly in charge of the Laboratories of Biochemistry of the Jefferson Medical College and Hospital, and of the Psycho-Biochemistry Laboratory, Graduate School of the University of Pennsylvania, and ABRAHAM CANTAROW, M D, Instructor in Medicine, Jefferson Medical College, Assistant Attending Physician, Philadelphia General Hospital, in charge of Laboratory of Biochemistry, Jefferson Hospital, with a foreword by ELMER H FUNK, M D, Sutherland M Prevost Professor of Therapeutics at Jefferson Medical College 454 Pages, 11 figures W B Saunders Company, Philadelphia 1932 Price, in cloth, \$5 50 net

This book is designed to correlate the established facts of biochemistry with the ordinary diagnostic problems of internal medicine. It is not a laboratory manual and accordingly is not concerned with the details of laboratory procedures. Rather it aims to give the clinician a clear understanding of the significance of the results of laboratory investigations within the field of biochemistry and related sciences. Light

chapters are devoted to consideration of the clinical aspects of fundamental metabolic processes in health and disease. Then follow ten chapters dealing with more highly specialized functions and the biochemical aspects of certain disease states. The final chapter is an outline of the chemical diagnostic features of various disorders, thus providing an indexed table of the clinical laboratory tests of a chemical nature which are informative in various disease conditions. The style is lucid, and highly technical discussions and matters which are yet largely controversial are omitted. Free use of section and paragraph headings in several styles of type emphasizes the logical arrangement. This is a well made book which promises to be very useful.

Physiotherapy Its Principles and Practice

By F. HOWARD HUMPHRIS, M.D. (Brux.), F.R.C.P. (Edin.), M.R.C.S. (England), D.M.R. and E. (Camb.), Hon. Consulting X-ray Physician and Electrotherapist to Christ's Hospital, Hon. Consulting X-ray Physician and Electrotherapist to the London Clinic, Late Officer in Charge X-ray and Electrotherapeutic Departments, 3rd London General Hospital, Capt. R.A.M.C. (T.F.), Late Consulting X-ray Physician to the Force in Egypt, Major R.A.M.C., Past President of the American Electrotherapeutic Association, Past Vice-President of the Section of Electrotherapeutics, Royal Society of Medicine, and RALPH E. STUART-WEBB, M.B., B.S. (Lond.), M.R.C.S., L.R.C.P., with contributions by FRANK ROMER, M.R.C.S., L.R.C.P., A. E. HAYWARD PINCH, F.R.C.S., M.R.C.P. and A. GORDON WATSON, M.D. The Macmillan Company, New York, 1932. Price, \$4.50.

Physiotherapy, as its full title indicates, is divided into two parts. In the introduction the author defines Physiotherapy as "the treatment of the patient by physical means, at the hands of the physician or by the art and skill of the surgeon" and he stresses the necessity of physiotherapists being medically trained. In the first part, "Principles", a very full and detailed description of the application and apparatus of the various physiothera-

peutic agents is given, as well as a brief historical review of the older methods, such as static electricity and low and high voltage currents. Infra-red rays, being antagonistic to ultra-violet and X-rays, may be used to some extent as preventive and curative of X-ray lesions, it is stated.

"Radium Therapy", which is Dr. Pinch's contribution, is a chapter of but 17 pages. One may well question the wisdom of attempting to present such an important subject in so small a compass. Ample warning is given as to possible complications and sequelae.

"Massage and Manipulation" by Dr. Frank Romer is well done. He wisely urges medical men to be sure that they give their patients no reason for going to a "bone setter". A doctor should know how to prescribe massage, and what particular cases need it. X-ray plates should be made of joints, before manipulation, to make sure that no pathological lesion exists.

Because in this country spa treatment is less known and less popular than in England and on the Continent, the discussion of this method of physiotherapy is of interest. One wonders, however, about the wisdom of the inhalation of radio-active waters over several days, in view of recent knowledge of the effects of fixation in the skeleton. Dr. Watson aptly states that "all mineral waters cure some cases", although he feels that at present the claims of spas are too conservative. Quite naturally he stresses the advantages of the British spas. Melted paraffin-wax baths and foam therapy are less common physiotherapeutic agents.

Under "Practice" the use of physiotherapy and what may or may not be accomplished in various disturbances and diseases is considered. One feels that some statements of the results seem at times over-enthusiastic, but the gratifying effects in poliomyelitis we know are not exaggerated. Particularly interesting is the description of Krowler's method in the treatment of tuberculous laryngitis, "in which the patient himself directs a beam of sunlight down his own throat by means of an ordinary looking-glass and a laryngoscopic mirror, for about an hour a day". This has been used by some laryngologists in this country with

decidedly good results. Dermatological use of physiotherapeutic agents is so general as to require no comment. The last chapter on the treatment of "Various Diseases" is of some present day importance to the devotee of sports, as golfer's back, motorist's heel, rider's strain and tennis elbow are all optimistically treated.

Throughout, the author insists that the physiotherapist cooperate with the physician and surgeon. The book is of general interest and value to all practitioners, and of real practical assistance to one whose special field is physiotherapy. R C W

Conquering Arthritis. By H M MARGOLIS, M D, x+192 pp, 3 illustrations. The Macmillan Co., New York City, 1931. Price, \$2.00.

"Conquering Arthritis" is the somewhat optimistic title of another of the growing stream of books written for certain classes of patients by specialists in the particular disease discussed. Readily comprehensible to the intelligent reader and written by experts without the bias of commercial interests, they do much to aid the physician in his professional duties and may prove to be invaluable to his patients. Faced with a problem made unusually difficult not only by its own complexities and uncertainties but also by the necessity of using non-technical phraseology, the author has produced a work which, with a minimum of dogma, succinctly and unemotionally states the present knowledge of the genesis and treatment of arthritis. After a brief review of the history of the disease, the discussion of chronic arthritis is introduced by a simple classification, the following forms being recognized: (1) Senescent arthritis, (2) static arthritis, (3) metabolic arthritis, and

(4) infectious arthritis. Each of these forms is treated separately but the greater portion of the book is devoted to the fourth class, with a somewhat extended discussion of the relation of focal infection to inflammation of joints. Especial emphasis is placed upon the teeth and tonsils as foci of localization of streptococci. While the author treats this subject quite dispassionately, nevertheless the uncritical reader might well receive the impression that laboratory animals may show arthritic changes when injected with organisms from human focal infections irrespective of the mode of injection and further, that such changes, when they occur, constitute proof of the existence of arthrotropic organisms. The author considers the patient's genetic background exceedingly important in the etiology of chronic arthritis. Stress is laid upon various forms of treatment and the necessity for adjusting the therapeutic measures to the patient as well as to the known or surmised etiological factors. Margolis feels that available therapy is of great value even in advanced cases. Dietary, physiotherapy, and medicinal procedures are explained with conservative opinions as to probable results. This phase of the subject is developed very well, for although much information relative to treatment is given, there is nothing which would tend to induce or enable a patient to treat himself without the advice of his physician. Just as manuals on diabetes mellitus, on nutrition, and upon other subjects have served to bring the physician and his patient into a clearer understanding of their mutual problem, so this book should be of distinct value in the treatment of intelligent patients with chronic arthritis.

J C B

College News Notes

Dedicatory exercises for the new Medical Laboratory Building of the University of Texas, the John Sealy Hospital Outpatient Building and the Rebecca Sealy Residence for Nurses were held at Galveston, May 30-31, 1932. Dr George E Bethel (Fellow), Galveston, delivered the address of welcome. Dr M L Graves (Fellow), Emeritus Professor of Medicine of the University of Texas, presented two clinics, and Dr L F Barker (Fellow), Emeritus Professor of Medicine at the Johns Hopkins University School of Medicine, gave a medical clinic.

Mrs Helen Felch Jennings, wife of Dr Charles Godwin Jennings (Master and Second Vice President of the College), died suddenly immediately following the San Francisco Clinical Session. Mrs Jennings was a daughter of Alpheus Felch, Fourth Governor of Michigan, a descendant of one of the early settlers of that State.

Dr Walter A Bastedo (Fellow), New York, Dr Oscar Bethea (Fellow), New Orleans, Dr Charles L Brown (Fellow), Ann Arbor, Dr Henry Christian (Fellow), Boston, Dr Bernard Fantus (Fellow), Chicago, and Dr Virgil E Simpson (Fellow), Louisville, attended a meeting at Philadelphia, April 30, as members of the Sub-Committee on Scope of the United States Pharmacopoeia Revision Committee. This Committee is now selecting the newer remedies for the Pharmacopoeia. Many of these are patented, and over such the Pharmacopoeia can exert no control. As their titles and descriptions are legalized, the Committee can make such a remedy official only if the patentee agrees to every word of the text used by the Pharmacopoeia and agrees to abide by the standard so set for his product. In many cases, this agreement is refused. In some cases where it is accepted, manufactur-

ers of allied products claim an equal right to a place in the Pharmacopoeia, on the ground that pharmacopoeial recognition of only one member of a class would be unjust discrimination and would afford an unfair advertising opportunity.

Dr F M Pottenger (Fellow and President of the College), Monrovia, Calif, gave an address at the annual meeting of the State Medical Association of Texas at Waco, Texas, May 7, 1932, on "The Relations of Tuberculosis to General Medicine".

The Central Tri-State Medical Society, composed of physicians of Kentucky, Ohio and West Virginia, recently conducted its annual meeting. The entire scientific program was offered by Fellows of the College, as follows:

Dr Walter Freeman, Washington, D C
—"Conservative Treatment of Head Injuries",

Dr J Shelton Horsley, Richmond, Va—"Cancer of the Stomach",

Dr Charles H Cocke, Asheville, N C
—"Certain Phases of the Healing Process of Tuberculosis".

Dr Louis F Bishop (Fellow) and Dr Louis F Bishop, Jr (Fellow), both of New York City, took part in the scientific exhibit at the meeting of the American Medical Association, New Orleans, May 9-13. Their exhibit consisted of electrocardiograms with descriptive titles on Vertigo and Syncope in Cardiac Arrhythmias.

An examination of the Program of the annual meeting of the American Medical Association discloses that eighty-nine Fellows and four Associates had official assignments.

Dr J Burns Amberson, Jr (Fellow), Assistant Professor of Clinical Medicine,

Columbia University College of Physicians and Surgeons, was the guest lecturer and delivered a didactic lecture each day, followed by bedside instruction, in connection with the Five-Day Postgraduate Tuberculosis Institute League at the Jersey City Medical Center, May 16-25, under the joint auspices of the Hudson County Medical Society, Hudson County Tuberculosis League and the Hudson County Tuberculosis Sanatorium and Clinics. Dr. Amberson's subjects were Pathology and Pathogenesis.

Dr. Asher A. White, son of Dr. S. Marx White (Fellow and Ex-President of the College), has been awarded the Alexander Cochrane Bowen scholarship in medicine, and will spend next year with Dr. Francis R. Fraser. The scholarship affords opportunity for one year postgraduate study and research at St. Bartholomew's Hospital in London. Dr. White received his M.D. degree from the University of Minnesota in 1929. He was interne and then resident in the New York Hospital for two years with Dr. Lewis A. Conner (Fellow) and Dr. Nellis Foster.

Dr. William H. Walsh (Fellow), Chicago, has been selected as the Medical Consultant of a new Medical Center at Monterrey, Mexico, by the Governor and Secretary of the State of Nuevo Leon. The new Medical Center contemplates a new medical school, a general hospital of five hundred beds, a nurses' home, a separate wing for tuberculosis, one for the insane, and another for communicable diseases. Dr. Walsh was formerly Executive Secretary of the American Hospital Association, and is now engaged in hospital planning, organization, management and equipment.

Dr. Frederick J. Farnell (Fellow), Providence, R. I., Chairman of the Public Welfare Commission of the State of Rhode Island, is the author of the following articles which appeared recently in the United States Daily

"Task of Reshaping Characters of Paupered Convicts",

"Conflict of Prison Industries with Products of Free Labor",

"Sanitation as Crime Preventive"

Dr. Frank Parsons Norbury (Fellow), Jacksonville, Ill., was initiated to honorary membership in the Illinois Epsilon Chapter of Phi Beta Kappa fraternity recently. Dr. Egerton L. Crispin (Fellow), Los Angeles, Calif., is a member of the Alumnus Membership Committee of this national honorary fraternity.

The obituary notice for Dr. John Alden Lichty which appeared in the July issue of the Annals was prepared by Dr. Clement R. Jones, Regent. Through oversight the usual acknowledgement was not made.

Dr. Wann Langston (Fellow), Oklahoma City, Okla., appeared on the circuit postgraduate course of the University of Oklahoma, Extension Department, June 13-15, lecturing on the subject "General Vascular Disease, Hypertension and Myocardial Disease" at Clinton, Elk City, Woodward and Alva, Okla.

Dr. J. W. Torbett (Fellow), Martin, Texas, addressed the North Texas Medical Association at its regular semi-annual session at Bonham, Texas, on June 15 on the subject "The Intradermal Use of Bacterial Antigens for the Diagnosis and Treatment of Several Chronic Diseases." Dr. Torbett read a paper before the State Medical Association of Texas at its May meeting in Waco on the subject of "Peribronchial Glands as a Focus of Systemic Diseases."

Thurman Delna Kitchin (Fellow), Wake Forest, North Carolina, President of Wake Forest College, was recently appointed by Governor O. Max Gardner of North Carolina a Member of the Commission for the Improvement of Laws. In May of this year, Dr. Kitchin became a member of the Duke (Rho) Circle of Omicron Delta Kappa, and on June 8, 1932, the LL.D. degree was conferred upon him by Duke University.

Dr. Ray M. Balcutt (Fellow), Oklahoma City, addressed the Twin Lakes District Medical Society, Rockwell City, Iowa at its Tenth Annual Assembly, June 16, on the subject of "Diagnosis and Treatment of Allergic Diseases".

Acknowledgement is made of the following gifts to the College Library of publications by members

Dr Hyman I Goldstein (Associate), Camden, N J—1 reprint,
 Dr Algernon B Jackson (Fellow), Washington, D C—4 reprints,
 Dr H R Livengood (Fellow), Elizabeth, N J—1 reprint,
 Dr Robert U Patterson (Fellow), Washington, D C—1 reprint,
 Dr Clair L Stealy (Fellow), San Diego, Calif—1 reprint,
 Dr Samuel Weiss (Fellow), New York, N Y—1 reprint

Dr Robert U Patterson (Fellow), Surgeon General of the U S Army, was the recipient of the honorary degree of Doctor of Laws bestowed by his Alma Mater, McGill University, at the annual Convocation of that institution for the conferring of degrees on May 26, 1932

Dr Rock Sleyster (Fellow), Wauwatosa, Wis, was re-elected a member of the Board of Trustees of the American Medical Association for five years, during the New Orleans meeting, May 12

Dr C W Greene (Fellow), with Dr Frank A Hartman, Dr J J Maisel and Dr G W Thorn, all of the University of Buffalo, were awarded the gold medal by the Committee on Awards of the American Medical Association in connection with the scientific exhibit at the New Orleans Session, "for original investigative work on the development and use of a hormone from the suprarenal cortex and excellence of presentation"

Dr J Arnold Bargaen (Fellow), Dr P W Brown (Fellow), with Dr H M Weber, of the Mayo Clinic and Foundation, Rochester, Minn, were awarded the bronze medal, "for original investigation of diseases of the colon and excellence of presentation"

Dr Ross V Patterson (Fellow), Dean of Jefferson Medical College of Philadelphia, was honored, June 13, by Colgate Uni-

versity with the degree of Doctor of Science

Dr Mary O'Malley (Fellow), Washington, D C, was elected President-Elect of the Medical Women's National Association at the annual meeting of that Society in New Orleans, May 9

Dr Herbert L Bryans (Fellow) Pensacola, Fla, was recently reappointed a member of the Committee on Publication of the Journal of the Florida Medical Association

"A New Non-surgical Method of Treatment for Gastric and Duodenal Ulcer" was the subject of an address delivered by Dr L Winfield Kohn (Fellow), New York, before the New York State Medical Society's meeting at Buffalo, May 25, 1932

Dr Edward J Engberg (Fellow), St Paul, Minn, was re-elected Secretary of the Minnesota State Board of Medical Examiners for the term of one year, at the May meeting of the Board

Dr Ralph deBallard Clarke (Fellow), Meriden, Conn, presented a popular public lecture on May 4 on the subject of "What is New in Tuberculosis" to a group comprising parent-teachers' organizations, public health association members, classes from the Nursing School of the Meriden Hospital, and the general public. Compression therapy and collapse surgery were illustrated by X-ray films, as they were applicable to a series of tuberculous children and adolescents

Dr Joseph Rogers Darnall (Fellow), Major, Medical Corps, U S Army has been awarded the Order of the Purple Heart. Major Darnall was wounded in action during the Meuse-Argonne offensive, October 28, 1918. Major Darnall also received a departmental commendation for his foresight and work in preventing a possible epidemic during the emergency occasioned by water shortage in Zamboanga, P I, while he was stationed there as Surgeon in 1928

Dr Hyman I Goldstein (Associate), Camden, N J, read a paper entitled "Recent Ad-

vances in Treatment, Hemorrhagic Diseases, Anemias, Uremia and Dropsy, Muscular Dystrophies, Diphtheria, Chorea and Meningitis" before the Medical Society of New Jersey at its annual meeting in Atlantic City, June 16, 1932

Dr Elliott P Joslin (Fellow), Boston, Mass., addressed the annual meeting of the Fifth Councillor District of the Medical Society of the State of Pennsylvania at York, July 28, on diabetes

Dr Ada E Schweitzer (Fellow), Indianapolis, Director of Infant and Child Hygiene on the Indiana State Board of Health, conducted a Child Health Institute, Winona Lake Chautauqua, July 3 to 9, inclusive. The program was devoted to home protection and to the conservation of the child by the home in cooperation with the community and with organized lay groups and professional and official agencies

Dr Waller S Leathers (Fellow), Nashville, Tenn., was re-elected President of the Nashville Board of Medical Examiners for the coming year, during their annual meeting at Washington, May 2

Dr Alvin G Foord (Fellow), Pasadena, Calif., was made President-Elect of the American Society of Clinical Pathologists at its meeting in New Orleans, May 6-9

Dr William H Robey (Fellow), Boston, Mass., was recently elected President of the Suffolk District Medical Society

Dr Henry F Stoll (Fellow), Hartford, Conn., was elected President of the Hartford County Medical Association at its one hundred and fortieth annual meeting on April 5, 1932

Dr Cecil Lorio (Fellow), Baton Rouge, La., was made President of the Louisiana

State Pediatric Society at its meeting in New Orleans, May 10

THE 1932 GRADUATE FORTNIGHT OF

THE NEW YORK ACADEMY OF MEDICINE

Tumors, benign and malignant, will be the theme of the 1932 Graduate Fortnight of the New York Academy of Medicine to be held Oct 17-28. The medical profession of the country is invited to participate in the intensive two week study of this important medical and surgical subject. A full program of clinical demonstrations, lectures and conferences has been arranged to cover all phases of tumors, their diagnoses and treatment.

Concurrent with the Fortnight, and for an added week thereafter, there will be housed in the Academy building an exhibition of anatomical specimens numbering approximately 3000 units. A number of the sections in the exhibition will be subjected to lecture demonstrations at regular intervals.

Ten evening meetings have been arranged during which tumor growths in various parts of the human anatomy will be discussed. Among the speakers are included Doctors W Gordon M Byers, Edwin Beer, Charles A Elsberg, James Ewing, Donald C Balfour, Daniel F Jones, Dean Lewis and Francis Carter Wood.

Thirty afternoon clinical meetings and demonstrations have been arranged in eighteen of New York City's leading hospitals, including Bellevue, Lenox Hill, Presbyterian, St Luke's, Fifth Avenue, Post-Graduate, Neurological Institute and others.

There is no charge for attendance at any of the clinics or meetings, but registration is required for participation in the hospital demonstration clinics. A complete program and registration blank for the clinics and demonstrations may be secured by addressing The New York Academy of Medicine, 2 East 103rd Street, New York City.

OBITUARIES

DR LEONARD F C WENDT

Dr LEONARD F C WENDT (Fellow), Detroit, Michigan, died suddenly June 11, 1932, of heart disease at the age of 56 years

Dr Wendt was born in Detroit, the son of Henry R and Julia Wendt. He graduated from Baldwin University, Berea, Ohio, in 1896, receiving the degree of Bachelor of Sciences, and from the Detroit Homeopathic College in 1902, receiving the degree of Doctor of Medicine. He received the honorary degree of Doctor of Science at Baldwin University in 1928.

Dr Wendt was Chief of the Diabetic Clinic at Grace Hospital, Detroit, for fifteen years. He was also a member of the Executive Board of that hospital. During the World War he was Secretary of the local Medical Advisory Board, as well as its examiner. He was Grace Hospital's volunteer physician at Camp Custer. At one time he taught diagnosis and pediatrics at the old Detroit Homeopathic College, and during 1915 was Instructor in Physical Diagnosis in the Detroit College of Medicine and Surgery. He was Consulting Physician at Miriam Memorial Hospital and Attending Physician to the Eloise Hospital for Mental Diseases. Dr Wendt was the author of several monographs on diabetes.

He will be remembered for many years to come for his work among diabetic children. In their interest, he established a summer camp on a lake near Brighton, Michigan, in 1926. He continued this project each year with the help of the Red Cross and of Grace Hospital, but at great expense

to himself personally. Many children from Detroit and other parts of the State, who otherwise might have had to suffer their affliction in the heat of the city, have been greatly benefited. The camp will be continued and will be known as the Leonard Wendt Camp for Diabetic Children.

Dr Wendt was a member of the Wayne County Medical Society, the Michigan State Medical Society, a Fellow of the American Medical Association, a member of the Interstate Medical Society, the Michigan Trudeau Society, the Society for the Advancement of Science, and the Association for Internal Secretions. He had been a Fellow of the American College of Physicians since 1920.

(Furnished by WILLIAM M LEFEVRE, M D, F.A.C.P., Muskegon, Michigan)

DR FREDERICK WILMOT
MANN

Dr FREDERICK WILMOT MANN (Fellow), Houlton, Maine, died June 16, 1932, at the Aroostook Hospital following an emergency operation for acute intestinal obstruction. Dr Mann had seen his patients the day before, and had planned to leave for the annual meeting of the Maine Medical Association at Rangeley the very day on which his death so suddenly and unfortunately occurred.

Dr Mann was born at Baillie, New Brunswick, Canada, May 18, 1868, the son of Thomas Andrew Mann and Sarah Ann Gilmore. He was a graduate of the College of Physicians and Surgeons of Baltimore in 1892, and of the University of Bishops College

Faculty of Medicine of Montreal in 1900, receiving the degrees of M D and M D, C M, respectively. He first practiced medicine in Monticello, Maine, and then removed to Houlton, where he had practiced for over thirty years. He did postgraduate work at the Boston University during 1919 and 1920. He was a member of the Visiting Staff of the Madigan Memorial Hospital and the Aroostook Hospital, and had acted as lecturer to student nurses at both institutions for several years. Dr Mann was a charter member and ex-President of the Aroostook County Medical Society, a member and ex-President of the Maine Medical Association, a Fellow of the American Medical Association, a member of the British Medical Association, a member of the Council of Physicians and Surgeons of New Brunswick, Canada, and had been a Fellow of the American College of Physicians since April 8, 1929. In addition, Dr Mann was a Director of the Aroostook Anti-Tuberculosis Association, a member of the Houlton School Board (serving his second term—its Chairman during 1931) and a member of many local organizations.

Dr Mann was keenly interested in civic and educational affairs. He was an eager student of medicine, his counsel was often sought. His fund of amusing stories, his ability to quote poetry, his genial personality made him welcome in any group. Above all, he was one of the ablest internists of his state, and a brilliant physician.

DR BYRON FULLER BARKER

Dr BYRON FULLER BARKER (Fellow), Bath, Maine, died on April 29,

1932, from acute appendicitis. Dr Barker was born in Bath, November 19, 1872. He received the degree of Bachelor of Arts from Bowdoin College in 1893, and the degree of Doctor of Medicine from the Jefferson Medical College in Philadelphia in 1896. He was a member of the Medical Staff of the Bath City Hospital, and taught a course in Internal Medicine to the Nurses of that institution.

Dr Barker was an ex-President of the Sagadahoc County Medical Society, ex-Secretary of the Bath Medical Club, a member of the Maine Medical Association, the American Medical Association, and had been a Fellow of the American College of Physicians since 1931.

Quoting from the Maine Medical Journal, "His life was devoted to the practice of medicine, he read widely, had few if any, side issues, took short and few vacations and was a model of what a careful, cheerful, conscientious medical advisor should be. He studied the latest medical treatises and had them ready in mind for emergencies. He was keen in diagnosis, was trusted implicitly, and was a pleasing gentleman in the house of sickness."

(Furnished by E. W. GEHRING, M D, F A C P, Governor for Maine.)

DR BENJAMIN FRANKLIN SHUTTLEWORTH

Dr BENJAMIN FRANKLIN SHUTTLEWORTH (Fellow), died at his home in Clarksburg, W. Va., March 31, 1932, from cardiac failure, aged 54 years. Dr Shuttleworth was one of the most prominent physicians of the State. He received his Bachelor of

Arts degree at the West Virginia University before entering Jefferson Medical College of Philadelphia, from which he was graduated in 1905. Since graduation, he practiced in Clarksburg, where he was universally esteemed by the profession. Dr. Shuttleworth was honored by being appointed to the West Virginia State Council of Health. He belonged to the Harrison County Medical Society, and was an ex-Presi-

dent of the West Virginia State Medical Association. He was a Fellow of the American Medical Association, and had been a Fellow of the American College of Physicians since 1922. His wife, surviving him, was Miss Rachael Farris.

(Furnished by JOHN N. SIMPSON, M.D., F.A.C.P., Governor for West Virginia.)

Clinical Aspects of Gastric Secretion

By ARTHUR L. BLOOMFIELD, M D , F A C P ,
San Francisco, California

THE study of gastric secretion in man may be approached from either of two standpoints. First, there are the problems dealing with the mechanism of the formation of the various constituents of the gastric juice and with the variations of these constituents under "normal" or "average" conditions. Here we do not seek that utility which is implicit in clinical observations, we deal with a phase of animal (human) physiology. But there is another aspect which is of importance to the pathologist and to the physician, namely, the correlations which may exist between aberrations of secretion and disorders of structure or function of the stomach. This study is practical and empirical and it serves no purpose unless its results aid in diagnosis or lead to useful therapeutic action.

Ideas about the physiology of gastric secretion in man have been based largely on the results of animal studies. The pouch preparations of Pavlov and of Heidenhain modified by a host of pupils and followers still represent the usual method of study,

and while occasional observations on men with gastric fistulas such as those of Beaumont and more recently of Carlson have been recorded, most of the human studies have been carried on by clinicians with a view to developing diagnostic methods in disease. Physiologists working in this domain, curiously enough, seem disinclined either to use the human subject or to accept as sound the results of human studies, and a scrutiny of the recent literature suggests that those dealing with men on the one hand, and with dogs on the other, seem destined, like the parallel lines of Euclid, never to meet on common ground. None the less, we believe that by proper methods accurate measurement of the gastric secretions of men can be made and it is the present purpose to summarize the results of such studies both in normal people and in disease.

METHODS

Since the popularization of the stomach pump sixty years ago the gastric juices have been readily accessible for study, but bitter debates have been carried on as to what sort of stimulus is most appropriate for promoting a flow of juice. That it should be some sort of meal which the subject consumes seems to be agreed

Presented at the San Francisco Meeting of the American College of Physicians, April 4, 1932

From the Department of Medicine, Stanford University Medical School

upon by common consent despite the fact that such a procedure defeats its purpose at the start, pure secretions are then unobtainable and one recovers for study gastric juice mixed with a variable and uncertain quantity of foreign substance. Indeed the very essence of the procedure of the animal physiologist—the expedient of the isolated gastric pouch—was designed to evade this difficulty and to allow the collection of uncontaminated secretions. Within recent years pharmacodynamic substances, such as histamine, which powerfully stimulate gastric secretion and which can be administered parenterally have become available so that pure gastric juice can now be obtained from men under standard conditions. But in practice most clinical workers cling with almost sentimental tenacity to the idea that a meal of some sort must be eaten if the stomach is to reveal its true activities. The principal argument has been that histamine is unphysiological and that to test its function one must give the stomach normal work to do—namely, a meal. From the standpoint of the physiologist such a claim is, of course, absurd. One need only to recall that the standard stimulus used in animal physiology—the electric current—is one which the animal in nature does not encounter at all. Furthermore, who is to say what sort of a meal would constitute the normal for any particular person, certainly there is no reason to regard the usual doses of bread, gruel or meat as especially suitable. Rather it would seem important to abandon these anthropomorphic concepts of gastric activity and to invoke the basic principles which must

be fulfilled with any adequate functional test. The matter has been discussed in detail elsewhere,¹ but briefly, it may be said that the stimulus must be a uniform one capable of repetition under approximately identical conditions, that it must impose stress on the function to be tested and that in practice it must yield useful information. The ordinary test meals clearly fail to meet these specifications, they impose no tax which will bring out the maximum secretory capabilities of the stomach, they approach a standard stimulus only very roughly and the variable mixtures of food and gastric juice which are obtained for analysis are unsuitable for quantitative studies. Histamine, on the other hand, has made possible accurate estimations of gastric secretion; it fulfills all the criteria which have been enumerated above. If the drug is given hypodermically, pure gastric juice may be withdrawn from the stomach just as from a Pavlov pouch. The actual technic of the procedure has been amply described² and need not be reiterated here. Suffice it to say that if the total gastric secretions are aspirated by continuous suction after a suitable injection of histamine a constant sequence of events takes place in normal people. For the first few minutes there is no evidence of increased secretion but during the second ten-minute period the volume of juice is definitely increased and during the third or fourth period a maximum flow is attained which then gradually subsides. Coincidentally with increased rate of secretion the titratable acidity rises and reaches a peak, usually after 20 to 30 minutes. The maximum

amount of juice secreted during any one ten-minute period and the highest acidity attained after a standard dose of histamine are values which may be taken as substantial indices of the secretory capability of the stomach in question. If the technic of aspiration is carried out properly, beautiful smooth curves are obtained which reflect the accuracy of the procedure. A few sample curves are shown in figures 1 and 2.

CLINICAL PHYSIOLOGY

The first problem was to work out normal standards to be used as a basis for comparison with the results in disease. Details of such studies have

been reported elsewhere.⁸ Perhaps the most striking fact which emerged was the wide variation both of acidity and of volume of secretion which existed in a group of healthy people without demonstrable gastric disorder. To be sure, the majority of the values fell in a fairly narrow range but there were sufficient exceptions to make it clear that no rigid standards of normality can be laid down, indeed there are a considerable number of apparently normal individuals who secrete no juice at all but only a little mucus. All that one can do then is to plot distribution curves and to assume that the nearer the values in a test case lie to the mean the more likely they are

FIG 1

FIG 2

FIGS 1 and 2. Curves showing volume of secretion and acidity at various intervals after histamine stimulation (Bloomfield and Pollard, Jr. *Am Med Assoc*, 1929, xcii, 1508)

to be normal Such distribution curves of acidity and of volume of secretion based on the findings in 100 normal people are shown in figures 3 and 4 It is seen that the largest amount of juice secreted in a ten-minute period fell within the limits of 21 to 35 c c in about one-half of the subjects, but values from 5 c c to 70 c c were encountered So, too, with acid three-fourths of the values lie above 100 but some normals yield much lower figures Other interesting facts are the steady decrease in average volume and acidity with advancing years, and the differences in the sexes which have been pointed out by Vanzant ⁴

These findings in normal people lead to certain reflections as to the physiological significance of gastric secretion, clearly the process is of much less importance to the organism than is, for example, the secretion of urine or the regulation of the acid-base balance Indeed, one may reasonably take the view that gastric digestion in man is a matter of no great conse-

quence and that gastric secretion has failed to develop as a highly standardized process, some mammalian species, such as the rat, even though omnivorous, possess no acid gastric secretion at all (Pollard⁵), and certainly many people though devoid of gastric juice maintain perfect health and nutrition and suffer no digestive symptoms ⁶ The breaking down of food is adequately accomplished by the intestinal juices and experimental proof of this mechanism has been obtained by Hines in this clinic This concept is of prime importance to the clinician because, as we shall point out later, if the process of gastric secretion is normally somewhat variable it will clearly be difficult to interpret the findings in disease

BASAL SECRETION

So far we have considered the response of the stomach to a purposeful stimulus But the question of gastric secretion can be viewed from another angle, that of the fasting or basal se-

FIG 3

FIG 4

FIG 3 Distribution of highest ten-minute volumes of secretion from one hundred normal people (after histamine) (Pollard and Bloomfield Jr Clin Invest, 1931, ix, 651)
FIG 4 Distribution of highest acidity reached after histamine stimulation by one hundred normal people (Pollard and Bloomfield Jr Clin Invest, 1931, ix, 651)

cretion Even with the subject at rest and without food one must suppose that the secretory mechanism is still under the influence of stimuli whether mediated through the autonomic nerves, or by hormonal or other influences Such is actually the case, and there have recently been recorded systematic observations on the gastric juice produced by people brought as nearly as possible into the "basal" state and disturbed only by the passage of the aspirating tube? Under these conditions it was found that most normal people secrete some gastric juice, it may vary in amount up to 20 or more cc per ten-minute period and the acidity frequently is over 100 (titratable, phenolphthalein) Furthermore, the type of juice obtained from any person is much the same on successive examinations, it is, perhaps, an expression of the activity of his autonomic nervous system When the basal secretion is abundant and highly acid there is but little change after an additional stimulus, even such a potent one as histamine It may turn out that the basal gastric secretion can be correlated not only with other physiological characteristics but with disease as well, but as far as we know adequate studies on this point have not yet been made

PEPSIN

Many attempts have been made to develop clinical methods for measuring pepsin but no very satisfactory procedure has been devised because of the inherent difficulties of ferment titrations Pollard and Bloomfield⁸, using a more accurate modification of previous methods, measured the con-

centration of pepsin and the total output in normal people and in disease Roughly there was a parallelism between the presence of pepsin and the normality of the juice in other respects, that is, whenever acid was abundant there was always an adequate amount of pepsin In some patients with anacidity pepsin was still detectable but in insignificant quantities In no case have we found an abundance of pepsin in the presence of a deficiency of acid or vice versa Measurements of pepsin serve no purpose, therefore, in practical clinical work even though of interest from the standpoint of the physiologist and chemist

CLINICAL APPLICATIONS

We may now turn to the actual clinical uses of measurements of gastric secretion and again it must be emphasized that any conclusions which are reached are essentially empirical It is with the fruits of practical experience and not with theoretical questions that we now have to deal, and it may be said in advance that regardless of method the sum total of information of help in dealing with patients is meager The histamine test has the great advantage of at least yielding accurate data but the application of these data unfortunately is limited Rearrange one hundred pennies as one will, no more than a dollar will emerge It is essential that this be made clear because from time to time articles appear which becloud the real issue insofar as they defend by special pleading, one or another procedure such as the Ewald or the fractional gruel meal and give an errone-

eous impression as to the value of the information to be obtained from any test of gastric secretion

More in detail, the first question which presents itself is whether there is any correlation between the amount and acidity of the gastric juice and the patient's symptoms. This question must be answered in the negative. There is no feature of the patient's complaints which enables one to predict whether his secretion will be scanty or abundant, highly acid or poor in acid. It is true that the type of indigestion which is common in patients with peptic ulcer is often associated with the presence of large amounts of highly acid juice but so many people with identical symptoms have neither ulcer nor high acid that no valid correlation can be made. Furthermore, many individuals with no symptoms at all turn out to have an abundant highly acid secretion or perhaps no secretion at all. The syndrome of "hyperacidity" of the older writers had better, then, be altogether abandoned, especially as recent studies of the mechanism of indigestion show that the symptoms are brought about by motor and not by secretory difficulties.⁹

Turning next from digestive symptoms to anatomical lesions, is there any relation between disease and the type of gastric juice? Under three conditions only have we found a valid correlation. First, in true Addisonian (pernicious) anemia absence of gastric secretion, is, as everyone knows, an almost constant finding. Hence a normal stomach juice weighs heavily against this type of anemia although severe anemias of other varieties (hy-

pochromic) frequently co-exist with gastric anacidity. Secondly, with peptic ulcer, especially duodenal ulcer, both acidity and volume of secretion are usually above the average, and while this is not invariably true it is so frequent that *in a doubtful case* scanty juice of low acidity or absence of acid point strongly away from ulcer as the correct diagnosis. High acid, on the other hand, while *compatible* with ulcer does not make the diagnosis since many normal people have just as high acid values as are found in ulcer cases. With cancer of the stomach one finds just the reverse; anacidity or low acid is present in such a preponderance of the cases that in a doubtful case—say an obstructive lesion of the pylorus—high acid would point away from cancer and towards a benign lesion. Aside from these three specific diseases—pernicious anemia, ulcer and cancer—it must be admitted that in practice studies of gastric secretion have little meaning and as time goes by we find ourselves passing the tube with less and less frequency. As with many other "special tests" in medicine examination of gastric secretion should be done not as a purposeless routine but to answer a definite question and a question which the test is capable of answering. Thousands of gastric analyses—most of them probably inaccurately executed—are done each year without the remotest possibility of serving any useful purpose, whether the acid is high or low or for that matter absent, nothing is usually brought out which either helps with diagnosis or leads to constructive action.

The reader is already thinking of

the many reports on all sorts of diseases—diabetes, hyperthyroidism, arthritis, acne, gall bladder disorders, etc etc,—in which it is claimed that some characteristic aberration of gastric secretion exists. These claims we have been unable to confirm if an adequate technic is followed and if proper controls with due consideration of the age of the patients and other factors are used as a basis for comparison. Distribution curves of acidity and volume of secretion from a large number of miscellaneous cases which demonstrate this fact will be published shortly (Polland).

Finally, a question of interest is whether disease of the stomach leads to alterations of the gastric secretions. Is, for example, a cancer, as it grows associated with progressive diminution in the flow of juice and in its acidity? Hurst¹⁰ and Polland and Bloomfield¹¹ have presented evidence that such is not the case, nor is there any reason to believe that ulcer leads to increased secretion of acid. Rather is it true that

ulcer tends to occur in people who to begin with secrete an abundant highly acid juice just as cancer usually occurs in those who already have a "gastritis" with deficient secretion.

SUMMARY

Because of the wide variations in gastric secretion which are found in healthy people it is difficult to draw conclusions of diagnostic value in patients. This difficulty is enhanced by the crude test meal methods which are usually employed. In practice, measurement of gastric secretion is helpful in the diagnosis of pernicious anemia (and perhaps certain types of hypochromic anemia), of gastric and duodenal ulcer, and of cancer of the stomach. The "routine" employment of test-meals, even in the case of patients with indigestion, is useless, whereas an occasional well conducted measurement of gastric secretion performed to aid in solving a special diagnostic perplexity is sometimes of the greatest value.

Standards of Normal in Gastric Secretion

By WALTER C ALVAREZ, M D , F A.C P ,
Rochester, Minnesota

AFTER approximately fifty years of stomach pumping and busy filling of archives with countless papers on gastric analysis, it would seem as if everything worth doing must have been done over and over again. Actually years of search through the enormous literature led me finally to the conclusion that most of the work on standards of normal which should have been done at the beginning has never been done, or at least, has never been done with enough material or with the technic that would satisfy a modern biometrician.

The value of one gastric analysis
For instance. What is the value of one gastric analysis? Through what limits is the acidity of the gastric contents of an individual likely to vary from day to day? Ordinarily when a physician gets a report back from the laboratory he is likely to assume that the figures, 40 free and 60 total, represent data as reliable and unchangeable as those expressing body weight or basal metabolism. But are they so reliable? A search through the literature showed only one paper on the subject and in this the data were so presented that I

could not get the information I wanted.

Accordingly Vanzant and I² studied the secretion of two healthy young women daily for a month. In one, who was fairly phlegmatic, the range of free acidity was from 30 to 46 units and the range of total acidity was from 40 to 66 units. The figures tended to follow a curve which apparently corresponded with the menstrual cycle. In this young woman one gastric analysis would be of some value because the variability was sufficiently small.

The other young woman was more temperamental, and when, during the middle of the month of observation, she suffered a severe disappointment, she became much depressed, and coincidentally, the free acidity rose in a few days from a mean of approximately 36 to a high point of 60 units. It then dropped rapidly to 20, and after a swing back to 46 came to rest again about 36 units. The total acidity followed the same course. Obviously, in this woman a single gastric analysis made during the middle of the month would have been almost without value.

Standards of normal acidity at different ages in men and women
The next question was. What is normal acidity, and how does it vary in the

Read before the American College of Physicians, San Francisco, California, April 4, 1932. From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota.

two sexes and at different ages? In order to answer this question Vanzant and her associates³ collected data on gastric analysis from 3,746 men and women who were proved to be without organic disease in the digestive tract and otherwise in fair health, and arranged the figures in percentage distribution tables corresponding to five year age groups. Figure 1 shows clearly that gastric acidity rises rapidly during childhood. At puberty the free acid of boys increases faster than does that of girls so that at the age of twenty years the mode or most typical figure for the men is 46 and for the women 31. It is possible that this difference in acidity has something to do with the greater susceptibility of men to ulcer.

The mean and modal acidity of the men falls off with age until finally in the later years of life it coincides with that of the women. The curious feature is that only late in life does the modal or most typical acidity of women fall off, and in them the mean acidity never falls. This makes it seem unlikely that the decline of acidity in men is due to a slow atrophy of the gastric glands because one would expect age to work the same injury to women. Strange to say, Vanzant and her associates³ found a straight line increase in the incidence of achlorhydria (to the ordinary test meal) with age, in both men and women. In men the percentage varied from 0 at the age of twenty-five years to 23 at sixty years, in women the figures were 3 per cent at twenty years and 28 per cent at sixty years. After the age of sixty-five years the percentage fell off gradually, due perhaps to greater longevity of persons with normal gastric acidity.

A study of the percentage distribution curves of total acidities at different ages showed that they were bimodal, in other words, there were two peaks, one representing the group of persons who have free acidity and the other the group who have none. To the biometrician bimodality always suggests the probability that he is dealing with two different varieties of persons. In this case, one type of man has probably inherited a tendency to develop achlorhydria and the other has inherited a tendency to keep his acid throughout life. The difference may be like that which gives to one man even in youth a shiny bald head and to another a musician's mop which lasts into old age. Using the same simile, the gradual falling off of acidity in older men may correspond to the gradual thinning of the hair with age, a thinning which is usually more marked among men than among women.

A study of the range of gastric acidity in apparently normal persons shows that throughout middle life one can hardly speak of a pathologic subacidity unless the free acid titer is below 20 for men and below 10 for women. One can hardly speak of pathologic hyperacidity unless the titer exceeds 75 units for men and 56 for women.

It would seem also that the physician should be slow to alarm patients over the fact that they have gastric anacidity. He should remember that this peculiarity can be found in one of four apparently normal persons aged sixty years. He may with propriety watch the patient with greater care than he otherwise would, but he

need not give expression to gloomy forebodings

The age curve of acidity is shifted bodily by disease Vanzant⁴ has shown that with duodenal ulcer the curves representing mean free acidity in men and women are raised about 12 points but otherwise left unchanged. This is a most interesting point, indicating as it does that these curves represent some biologic peculiarity which is too deeply rooted to be altered with ease.

Now that standards of normal are available I believe that the gastroenterologist should give up the old, cumbersome, arbitrary and inadequate classification of data from gastric analysis into acid, subacid, normal, and hyperacid, and substitute the method used by students of basal metabolism. Only as we physicians come to express acidities in terms of a percentage above or below normal can we obtain accurate knowledge in regard to the influence of different diseases and different types of ulcer in gastric secretion. Work along these lines is now being done on a large scale by Vanzant and her associates. It will be reported later.

Studies in regard to pepsin in health and disease Although much work was done years ago on the amount of pepsin in the gastric juice, it was of doubtful value on account of the crudeness of the technic used. Recent studies with a highly accurate technic¹ have led us to hope that the estimation of pepsin may give to the clinician information of greater value than that obtainable from a study of the acidity. With the method used, the usual value found in normal persons with a fairly calm temperament is about 90 units,

whereas the range is from 0 to about 500 units. In persons of an active, nervous, and tense temperament the values range up to 2,000 units. In patients with tractable duodenal ulcer the upper limit is about 800 units, and in patients with intractable duodenal ulcer almost all the readings are very high. It is possible, then, that this test will prove to be useful in helping the physician and the surgeon to recognize early those cases of duodenal ulcer in which treatment of any kind is going to be difficult. A study of the acidity alone is not so helpful because there is not enough difference between the values obtained in persons with tractable and in those with intractable ulcer.

Obviously a study of the gastric ferments cannot be of value in the diagnosis of ulcer because persons with a tense nervous temperament or with pseudo-ulcer commonly have as much pepsin as is found in the gastric juice of patients with an actual lesion in stomach or duodenum.

SUMMARY

Data have been published which throw light on the size of the daily variation in gastric acidity and on the reliability of one gastric analysis. In some persons the variation is so large that little value can be attached to figures obtained from one test meal.

A figure has been published which shows the range and central tendency of measurements of gastric acidity for men and women at five yearly intervals from youth to old age.

The mean acidity of men during middle life is about 15 points higher than that of women. The percentage

of persons with an acidity, after an Ewald test meal, increases steadily from youth to old age. The bimodal distribution curves representing total acidity in the various age groups suggest that there are two varieties of the human race: one with a tendency to maintain free acidity in the stomach, and the other with a tendency to lose it. The range of normal variation is so great that it is only an occasional gastric analysis that can be of any diagnostic value.

The curves representing mean free acidity in men and women from youth to old age are raised about twelve points but otherwise are unchanged by ulceration in the duodenum.

Persons with a nervous temperament commonly have pepsin values from fifteen to twenty times the normal. Similar values were found in most of the patients studied with intractable duodenal ulcer. Patients with tractable ulcer had pepsin values usually less than nine times the normal.

FIG 1 The range (including 80 per cent of the data), and central tendency of free and total gastric acidity in normal men and women by five year age periods from youth to old age

“Medicine” of the American Indian

THE theologico-physical dualism of the American Indian is best illustrated by his use of the word “Medicine” To the person brought up in the European tradition, medicine connotes some chemical, some regime of life or physical procedure used for its actual alternative effect on the body To the Indian the term means much more He may use the word to refer to an herb or drug, but more often it means some supernatural article or agency which may be of aid in curing disease or just as often the same thing may be invoked to insure the success of some individual or tribal undertaking Anything under the sun might achieve such therapeutic or mystical quality, might become “medicine”. Once invoked, the article thus dignified was held to be powerful and sacred It might be an animal, a bit of wood, a finger from a powerful foe, a spear or a pipe But once consecrated, it was never harmed if animal, or never again used for lay purposes if it were a utensil This did not mean that the article was revered in itself as the Indian was always careful to distinguish the fact that its symbolism alone hallowed it These articles or herbs or even formulae which were supposed to have healing or other benign properties were spoken of as “good medicine”, while evil influences or things were referred to as “bad medicine”

Asthenia: Clinical Types and Principles of Therapy

By EDWARD L. BORTZ, M D , F A C P , and
GEORGE MORRIS PIERSOL, M D , F A C P
Philadelphia, Pa

IN THESE times of stress with life being lived at an ever increasing pace and with financial burdens, familial cares and a multitude of other distressing factors putting a strain on the physical, mental and emotional powers, the subject of asthenia has become an important one. The term "Asthenia", in common with a number of the other terms current in medical parlance, is not used critically but is applied without discrimination to all types of weakness, debility, depression, constitutional inadequacy, or even nervous instability. It is customary to regard as asthenia, the state of weakness manifested in the course of convalescence of most serious illnesses, but in many cases this is simply a condition of general debilitation in accordance with physiological law which will disappear as the organism with the aid of diet and the proper hygiene is able little by little to recover its muscular and nervous force. Certain of the severe infections and intoxications, however, are definitely "dysthenizing" agents and the patients experience a true, pathological asthenia as a complication of their disease. Emotional

shocks, worry and prolonged nervous strain are also able to produce asthenia.

The basis of all physiological life is the maintenance of a balance between two or more counteracting forces and as a result there is the equilibrium in endocrine function, in the production of epithelial and connective tissue cells, in vasoconstriction and dilation, acidity and alkalinity, in the heat regulation of the body. The two states of asthenia and hypersthenia seem to be but variations of the normally maintained eusthenic state. Asthenia has been rather aptly styled a diminution of "potential". All energy produced by the metabolism is organized and distributed by the nervous system and just as electrical apparatus may be "geared" at high speed or low speed, human beings may experience an habitually increased influx of nervous force into the muscles and brain and be hypersthenic, or the influx may be less than is the portion of the normal individual and they will be classed as hyposthenic or asthenic. Asthenic individuals may have no discoverable functional disorders and no especial worries or cares, yet they fatigue more easily and rapidly than the normal person while the hypersthenic subject

Presented at the San Francisco Meeting
of the American College of Physicians,
April 5, 1932

may be of ordinary stature, development and function and may even show a low arterial tension, yet he is able to accomplish an enormous amount of work without notable fatigue, due to the tremendous amount of dynamic force which he possesses. A certain degree of asthenia and hypersthenia are exhibited in the course of routine existence and there are variations from day to day in the normal person's dynamic state. Usually this variation is confined within narrow limits but when it passes beyond these limits it becomes abnormal and there may result an asthenia so profound as to resemble stupor or an hypersthenia reaching almost to the point of mania.

The changes in the dynamic state from normal to pathological might be classified as follows

Hypomania
Exaltation
Hypersthenia
EUSTHENIA
Hyposthenia
Asthenia
Stupor (?)

Asthenia¹⁻⁴ is a well-defined state in which there is an insufficient influx of nervous force to support either muscular or intellectual effort, and in which the least movement or expenditure of energy provokes an overwhelming fatigue. Rest and sleep do not alter or improve the condition; diet and medications are of no avail. The asthenia includes both striated and smooth muscle fibers and the digestive system is subject to the same abnormal state of easy exhaustion. There may be slowing of respiration due to asthenia of the diaphragm. Londe⁵ finds that there is feebleness of the voice or com-

plete aphony, that the physiognomy becomes dull and the eyeballs sink in the orbits due to insufficiency of the muscle of Muller. There is no dulling or confusion of the mental processes and no loss of perception, although the patient may be unable to read, write, engage in conversation or follow a direct line of thought due to the fatigue which is engendered.

Asthenia is a purely functional state and may even appear without discoverable organic or emotional cause, at autopsy no trace is left on the organism. Benon⁶ states that it is remarkable to note the rapidity and completeness with which the asthenia may develop in a few hours or days, its immobility and invariability for an indefinite period of time, and its disappearance as rapid as its installation. It may last but a half-hour or it may become chronic and permanent, the attacks may last for a few months or for a year or two, then disappear and recur at a later date. Where there has been one prolonged attack of asthenia and the patient has returned to a normal state, it may be assumed that there will be a recurrence. Tastevin⁷ reports three interesting cases of primary, uncomplicated asthenia, in one of which the condition was permanent and in the other two was recurrent with periods of normal health intervening.

I. The first case was a young man 33 years of age. He had been a lively, active child but at the age of 14 years, when he was a student at the Sorbonne, he felt himself progressively growing weaker following frequent painful headaches and intellectual overwork. For some time he tried to continue his studies but having reached the age of 21 and finding this state persisting he attempted suicide and was interned in an

institution He left the institution after a time in exactly the same physical state but resigned to his situation When the case was reported some years later, the patient had been in a state of permanent asthenia for 15 years, all his movements were slow and he became fatigued with the least effort He described his malady as a feebleness of the nervous system with headache, inertia, lack of energy and decision It took him two hours to undress himself When he tried to read, his headache augmented and he was obliged to stop It was in bed that he was best His sleep was normal In the beginning when he was a student, he worried over his condition but now he cared for nothing, he had no interests and merely lived from day to day

II A woman, 74 years of age, had been in an institution for eight years following an attempt at suicide in the course of an attack of asthenia At the age of 24 years, being newly married and pregnant, she had had an attack of asthenia lasting nine months, following numerous difficulties with the parents of her husband From that time, there had been recurrences almost every year, lasting about six months and coming on at any period of the year The condition came on almost insensibly and disappeared in about the same manner, within four or five days she found herself ill or cured During the attacks she remained in her chair inert, she did not wish to talk, would have liked to read but after four or five lines could no longer recall what she had read and after commencing several times put aside her book She was tormented by her condition, her one fixed idea was her malady When she was 66 years old, feeling discouraged at having spent her whole life in this way, she tried to jump from a fifth story window, and had been interned in an institution for the eight years following During the last five or six years there had been no recurrences During the attacks, this patient had rachialgia and constipation but despite her age, there was no weakening of her intelligence

III A woman, 49 years of age, 12 years previously had had an attack of asthenia lasting 18 months Several years later, there was another attack, and sometime after that

a third Eighteen months after the third attack, she found herself again in this state and feeling it was better to die, tried to take poison and was interned in an institution She said that at these times she suddenly experienced a powerlessness to act, she wished to do things but had not the force to accomplish what she wished to do Her appetite was good but it was necessary for someone to feed her She remained apparently stupified in her chair, reading fatigued her too much and writing was worse There was a complete lack of ideas and her memory failed her, she responded to questions but liked better not to talk During the attacks there was no headache but stiffness and constipation existed She was well for variable periods of time and then this all recommenced, the asthenia disappeared in a few days

It is notable that in every instance the attempted suicide was not because of any mental aberration but because of anxiety and discouragement over the condition Tastevin states that the patients may be completely unmoved by what goes on about them, good or bad, but they have an excessive tendency to worry about their own incapacity, which will be manifested according to whether the subject is of an equable, irritable, impatient or anxious temperament

There are two forms of asthenia, the severe objective form described above and a light, subjective form in which the individuals are able to mask or overcome the asthenia and engage in business or follow a routine of social activity In the course of general practice in this country up to the present time, asthenia of the objective type has probably been observed most frequently as a complication of various acute disease states

For example in a recently treated case of intercostal neuralgia lasting less than two

weeks, after the pain and other manifestations of the illness had disappeared, the patient found herself in a state of objective asthenia. This extreme weakness was obviously not due to debilitation, the patient and her family believed that she had recovered from her illness yet she was prostrated on the slightest exertion. After an attempt to dress herself or comb her hair, she fell on the bed exhausted and gave up all thought of activity of any sort. The asthenia persisted for about two weeks, then disappeared and the patient returned to her usual routine of household and social duties.

In another case, the patient had acquired a severe streptococcic infection in his hand, with the institution of proper treatment, the infection was controlled fairly promptly but for two or three weeks the least effort provoked an overwhelming fatigue which it was impossible to combat.

The prostration following an attack of grippe is an outstanding example of asthenia. Andrews⁸ in an interesting article on grippal infections pleads for more serious consideration of the extreme weakness and cardiac instability following an apparently trivial attack of grippe. He states that he is often consulted by individuals who have not been well since an attack of grippe as long ago as 10 years yet the patients emphasize that they were not critically ill. The following case reported by Benon⁹ appears to be an instance of the failure to identify post-grippal asthenia, and the consequences which may be expected if the patients are not kept at repose until the regulating neurosthenic mechanism has righted itself.

This was a man, 31 years old, in whom the asthenia had developed at the age of 12 years and had become chronic and incurable. There was no family history of nervous disease. As a child the patient had had no serious disorders and his physical and mental development were normal. When he was

12 years old, he had an acute illness the exact nature of which is not known, he had a severe cold with fever and cough, remained in bed only a few days and no doctor was called. From that time there had been no infection, intoxication, traumatism or emotional shock, but although he was never really ill, he complained of the most diverse maladies and consulted all the physicians in the neighborhood without obtaining any relief. He was incapable of performing any heavy work or of earning his living although his intelligence was normal. He presented symptoms of *general nervous asthenia*, complaining of fatigue, weakness, headache, backache, gastric pains, diarrhea, constipation, loss of memory, insomnia, numbness and buzzing in the ears. He was unable to read because his vision became cloudy after a short time. He stated that he had not been strong since he was 12 years old and had grown without becoming any stronger.

Perhaps the largest group of patients showing a true objective asthenia which has become permanent are those who have never returned to their normal state after having influenza in 1918. These patients are receiving a great deal of attention at the present time both from the medical profession and the pharmaceutical laboratories, but here also the condition is not recognized as asthenia. The subjects are said to be suffering from constitutional inadequacy, functional depletion of the adrenal mechanism, disturbed thyroids, or chronic invalidism of indefinite origin, and their symptoms are listed as lack of strength, loss of initiative, subnormal temperature, low blood pressure, poor circulatory tone, weak action of the heart, weakness of the voluntary muscles, nervous depression, etc.

Rogoff and Stewart¹⁰ in a study of Addison's disease cite seven cases of adrenal cortex deficiency. The seventh

case in this series seems to be a typical case of post-influenzal asthenia

This patient after six months in a state of objective asthenia sought hospital care for the persistent weakness and fatigue. Repeated roentgenographic and laboratory examinations were made. He was given dilute hydrochloric acid, iron and arsenic, suprarenal gland and ephedrine but there was no improvement in the condition. With the administration of cortical substance the patient improved but it is possible that the benefit was derived from the systemic effect of the cortical hormone, the most important function of which is to spur oxidation and further metabolism generally, and not to any direct effect on the asthenia.

Asthenia, then, cannot be confused with states of debilitation since profound asthenia may be noted where there is no debilitation and a state of debilitation may exist with no evidence of asthenia. There are certain factors which are able to produce asthenia and which might be called "dysthenizing agents." Intellectual and physical overwork, pain, disturbing emotions, certain fevers, infections and intoxications such as pulmonary tuberculosis, syphilis, typhoid fever, botulism, or malaria, the important events in the sexual cycle, may all be followed by asthenia of variable intensity. Benon⁶ states that in the case of severe shock or trauma to any part of the body, if at the time of the shock or wound there has been cerebral disturbance with a total loss of consciousness of short or long duration, the patient is liable to a subsequent chronic asthenia. Yet maladies of the brain, itself, are not necessarily accompanied by asthenia and it is not unusual to see a completely shattered nervous system without a trace of asthenia. In tabes neither the ataxia nor the hypotonia

seems to produce asthenia, in Parkinsonism there is asthenia associated with rigidity and hypertonicity. The paralysis which is an almost constant finding in diphtheria has been spoken of as a form of asthenia but here there are definite and well-marked lesions of the spinal cord and peripheral nerves. A natural temporary asthenia is often noted in adolescents during the period of growth.

TABLE I
DYSTHENIZING FACTORS

- 1 *Pain*
- 2 *Overwork*
physical
intellectual
- 3 *Stroke*
- 4 *Total loss of consciousness*
from trauma to head, trunk or members
from shock
- 5 *Strong emotions*
anxiety and worry
familial
financial
vexation
anger
fear
jealousy, love, hate
religious fanaticism
- 6 *Neuropathies*
nervous affections
neuroses
psychoses
migraine
- 7 *The important sex epochs*
probably the chief physiological factor in contrast to the many pathological factors
asthenia may occur during growth
hyposthenic and asthenic children may be transformed after puberty¹¹
diminution or cessation of sexual activity may cause asthenia
menopause
ablation of ovaries
castration
asthenia may be noted immediately after pregnancy¹²

- 8 *Glandular insufficiency or over-activity*
exophthalmic goitre
Addison's disease (?)
- 9 *Intoxications*
coli-bacillosis (?)
alimentary (spoiled meat, poisonous mushrooms, botulism)
gases (CO₂, war gas)
drugs (sublimite, antimonial tartar, etc)
- 10 *Infections (fever in general is accompanied by asthema)*
influenza and grippe
typhoid fever
puerperal fever
malaria
tuberculosis
syphilis
acute articular rheumatism
exanthematous typhus
cerebro-spinal meningitis
epidemic lethargic encephalitis
uterine infections
dysentery
myocarditis
chronic focal infections
streptococcus infections
- 11 *Certain anemias and malignancies (?)*
- 12 *General disturbances of nutrition (?)*
pancreatic
diabetes
hyper- and hypo-glycemia
hepatic
hepatitis
azotemia
icterus
cholemia
renal
uremia
albuminuria

Asthemia of the subjective type is probably quite common but it may be so vague as to be difficult to distinguish. It may be either constitutional or acquired and like the objective form it may be temporary or chronic. The constitutional asthenic is an individual who does not appear ill; he possesses a certain degree of health but is incapable of augmenting his capital

of energy by exercise, diet or hygiene as a normal person may do. These persons spend their lives guarding against fatigue, they recognize their limitations and avoid crowds, exercises and sports, and fatiguing pleasures. An acquired subjective asthenia is most frequent where there is a *chronic infection* or as a *sequela of infection*. There is the same feeling of fatigue and the inability for sustained physical or mental effort but where the condition is permanent, there is a variability in intensity and the individuals are able to mask the asthenia or overcome it by force of their will. Periods of abnormal fatigue and insomnia may occur in the form of attacks with normal periods intervening.

Asthemics are subject to a particular form of insomnia which sedatives or narcotics can rarely overcome, the patients go to sleep readily at 9 or 10 o'clock in the evening but waken at 1 or 2 and remain awake the rest of the night. Headache and eye symptoms, gastric disturbances and constipation are frequent associated findings.

TABLE II
THE ASTHENIC SYNDROME

- 1 *Muscular asthema*
prostration and general weakness of both the smooth and striated muscles
inability to maintain a standing position for a very long time or make physical effort of any sort
a feeling of weight or heaviness of the body
repose or sleep does not make the fatigue disappear
loss of weight
- 2 *Intellectual asthema*
slowing of the intellectual process and inability for prolonged mental effort

difficulty of remembering and associating ideas because of the effort required

at times a sensation of emptiness in the head

the perceptions remain intact even though the asthenia may be so profound that the patient seems to be in a stupor

the patient has a perfect understanding of his state but cannot overcome it

3 *Emotional tendencies*

muscular and intellectual asthenia may exist independent of all emotion

two classes of individuals probably following their constitutional predisposition

a the calm resigned type

b those showing a disposition to "unnerving," irritability, or who feel a constant need to change their location

become sensitive and impressionable, believing that chance remarks or acts are meant to apply to them

show great anxiety over their condition and epigastralgia may follow with a sensation of painful epigastric constriction

4 *Nervous symptoms*

accommodative asthenopia is constant, is increased by work and disappears with repose

headache is very frequent

roaring or buzzing in the ears

dizziness

when head is lowered, when walking or when fatigued

vertigo with a fall is rare if not non-existent

insomnia

is habitual

of a particular type—the patient goes to sleep without difficulty at 9 or 10 but awakens at 1 or 2 and can sleep no more if he does sleep with the aid of drugs, he is troubled with nightmare and is prostrated on awakening may feel a need of sleep during the

day, especially when digestion is going on

rachialgia or lumbago

is frequent and at times severe

when localized in lumbar region, subject often believes he has a kidney affection

is increased by work or effort and eased by rest

5 *Visceral asthenia*

a *Gastric asthenia*

appetite may be good and food

may have natural taste but patient may not have the strength to feed himself

usual alimentation is badly supported

slowness of digestion

post-prandial weight or ballooning

aerophagia is frequent

it may be the gastric symptoms which fix the attention of the patient and cause him to consult the doctor¹

b *Intestinal asthenia*

constipation (may be a week or more between evacuations)

sometimes alternating constipation and diarrhea with mucous stools

c *Cardiac asthenia*

manifested more often by tachycardia than by bradycardia

palpitation especially after eating various disturbances of rhythm

tachycardia is not constant,

minor causes, physical or mental, produce an increase

in the pulse rate but after 3 or 4 minutes it returns to normal

arterial hypotension is the rule

6 *Genital asthenia is always present*

7 *May be signs of endocrine dysfunction, thyroid adrenal*

8 *Subjects are sensitive to the action of drugs*

only small doses are needed

condition is aggravated frequently by tonics and stimulants

HYPERSTHENIA

When studying the problem of asthenia, it must be borne in mind that for every degree of asthenia there is a corresponding degree of hypersthenia. There are cases in which, after the return to normal from a state of profound asthenia, the patients find themselves going into a directly opposite state of increasing muscular and intellectual hypersthenia, showing that the normal regulating mechanism has been suppressed. When the hypersthenia and asthenia appear in juxtaposition forming one attack, and are recurrent, the condition is spoken of as a "periodic psychosis," or as "periodic dysthenia" if they appear separately with normal periods intervening. Mania is regarded by some as the highest expression of hypersthenia, but Tastevin states that in these conditions of dysthenia, there may be extreme activity of the faculties with incessant need for movement, but there is no incoherence of ideas as in mania.

He cites the case of a woman, 30 years of age, who for two years had had attacks of "anxiety" coming on at variable intervals and lasting from one-half hour to a month or more. In spite of a total absence of emotional ideas or worries of any kind, during the attacks the patient was in the state of one who feared a calamity. It affected her as a weight on the chest which prevented her from breathing and as a constriction of the stomach. She felt impelled to move about, at night she tossed in her bed and if she slept for a while, she had nightmare. The feeling of anxiety left as suddenly as it came, after which the patient felt relieved but soon found herself in a state of complete asthenia. The duration of the asthenia was in proportion to the duration of the attack, with attacks lasting only a few hours, the asthenia was of short duration. After an attack lasting $1\frac{1}{2}$

months, the asthenia lasted 10 days. But, with attacks lasting over 3 weeks, after remaining prostrated for some days, she spent a short time in a normal state and then experienced a period of exaltation. She explained the sensation as a feeling of well-being, of being happy to live, she woke early in the morning and did not want to go to bed at night. She sang, laughed and thought of nothing but going out. The hypersthenia lasted about 5 days and she then returned to a normal state.

This case is classified as one of the psycho-neuroses, but it is interesting because when an individual wakes in the morning filled with the joy of living, he is inclined to attribute the fact to good digestion or to nicely balanced endocrine function. However, if this same feeling of alacrity and pleasure can exist as a pathological condition, one is forced to conclude that his dynamic state is not so well founded physiologically as might be supposed.

CONSTITUTIONAL DEPRESSION

Montassut and Delaville¹⁸ describe as "constitutional depression" a state which is easily recognized as one to which presumably normal individuals are liable, especially those possessing the "artistic temperament." In these subjects there is a daily rhythm of fatigue, the fatigue is original and it is chronic although of variable intensity in the course of existence. The awakening in the morning is difficult, somnolence at this hour is invincible and delays the hour of rising. Muscular activity is almost impossible, mental orientation and verbal expression are difficult, the reactions are pessimistic and there is a feeling of powerlessness and uselessness. With physical exercises or a cold bath the inhibition yields somewhat and as the

morning advances activity becomes easier. Luncheon is generally accompanied by an overpowering tendency to inertia. Toward the end of the afternoon when the normal person is beginning to tire, the fatigue disappears and is replaced by a feeling of animation. This is spoken of as the "5 o'clock cure." The feeling is not one of relief that the day's work is finished, since the same amelioration is noted during periods of vacation and it appears in individuals who do night work. With the "5 o'clock cure" intellectual activity becomes easier and more effective and is accompanied by a feeling of well-being and muscular agility. Dinner brings a temporary feeling of fatigue but this is more easily overcome. It is after dinner and often late into the night that he works with all his ability and with a slight intellectual excitation. The constitutionally depressed subject retires late and usually less fatigued and more optimistic than when he awoke. He realizes perfectly what his sensations will be after an intervening period of inactivity and the routine of fatigue and depression that he must undergo on awakening. This paradox of fatigue appears rather scandalous and the individuals get very little sympathy from their family and associates. One surmises that the old saying,

"When the sun has gone to rest,
The lazy man works the best,"

was inspired by the constitutionally depressed.

Warm baths, remaining in an overheated atmosphere, profound sleep, the lounging to which they are prone, and the probable change in body chemistry following the ingestion of food,

all aggravate the asthenia. Yet, although it seems necessary to contract a certain amount of physiologic fatigue in order to mask or neutralize the static and essential fatigue, work or effort cannot be pushed beyond a certain limit without producing a state of exhaustion.

NEURASTHENIA

The most important of "the asthenias" is neurasthenia, or nervous exhaustion. Benon¹⁴ believes that true neurasthenia has a special origin and evolution which distinguishes it from all the other asthenic states, and that this is solely the condition of general nervous exhaustion produced by muscular or intellectual overwork. Overwork is defined as a series of repeated and inadequately repaired fatigues which in time will produce a definite syndrome of the asthenic order. Beard,¹⁵ in 1868, was the first to isolate the condition of nervous exhaustion from the vast collection of neuropathic states and to give to the syndrome the name of neurasthenia. He found that most intellectual families possessed one or more neurasthenic members and that the condition was common among business and professional men, among women struggling to maintain a prominent position in society and among people of all types undergoing prolonged worry or nervous strain. But Beard observed that sunstroke might produce this same state of nervous exhaustion. It is true also that while such diseases as typhoid fever may be followed or complicated by a temporary, objective asthenia, after a very severe case of typhoid fever just as after a severe

surgical operation or a serious obstetrical case, the patient may never be able to recover from the nervous exhaustion but will spend the rest of his days in a state of neurasthenia with the easy fatigability, the various subjective mental and nervous symptoms and the sudden and unexpected giving away of his strength. After a close observation of a large number of cases, Beard listed the symptoms as follows, stressing that no symptom was constant and that only a few or almost all might be found in individual cases:

TABLE III
SYMPTOMS OF NEURASTHENIA

The symptoms may be divided into 3 groups, general symptoms, those which are evidences of cerebral exhaustion (cerebras-thenia) and those which are evidences of exhaustion or irritation of the spinal cord (myelasthenia)

I General Symptoms

1 *A feeling of profound exhaustion*

neurasthenics must keep to an ordinary routine as they become quickly wearied with attempting anything new

the treacherousness of nervous exhaustion is one of its most constant characteristics, in the morning subject may be able to work, walk or study but suddenly and from no traceable cause all strength may leave

2 *Deficient mental control*

inability to concentrate

lack of will, courage and self reliance

tendency to worry and fret over trifles

subject to attacks of mental depression lasting but a short time or for a day or more

may be a feeling of hopelessness even in the early and mild stages

wrong word slips in ahead of the one intended

subject to morbid fears

patient may be well aware of his weakness but cannot free himself from these

may have fear of storms, of going in any one direction, of traveling, of open places or of close and narrow places, a dread of society, of being alone, of responsibility, a dread of being afraid, fear of disease (hypochondria), of dust (will not sit down until chair is well dusted and may get up in the night and dust his clothes)

3 *Insomnia*

patient may have no difficulty in going to sleep on retiring but soon wakes and remains awake

may be hours before falling asleep, then sleep the rest of the night

may sleep fitfully with unpleasant dreams and a painfully active mind

may sleep only at night and never by day no matter how wearied

may sleep during the day though especially wishing to keep awake and stay awake all night

may be subject to drowsiness which does not come to actual sleep, dull, heavy, sleepy without the ability to go to sleep

in extremely rare cases, sleep may be normal

4 *Sick headache*

5 *Frequent blushing*

a common effect of nervous exhaustion

from the slightest physical or mental cause

may last months or years and disappear as suddenly as it began

6 *Localized peripheral numbness and hyperesthesia*

7 *Difficulty of swallowing*

8 *Hemi-neurasthenia* (may affect one side of the body more than the other)

9 *Rapid decay and irregularities of the teeth*

10 *Tremulous and variable pulse and pal-
itation of the heart (irritable
heart)*

rate and quality vary during
counting
in exceptional cases, pulse is very
slow (40 or less)
there may be alterations in pulse
rate between very high and very
low
cardiac action is powerfully affected
by the mind and under the influ-
ence of the emotions
pulse is frequently compressible

11 *Nervous dyspepsia*

is most commonly found with the
nervous diathesis and may be the
forerunner of a long list of ner-
vous symptoms through all the or-
gans, the eyes, ears, brain, spine
and reproductive system
nervous dyspepsia may take the
place of many other symptoms,
being better when they are worse
and worse when they are better
is relieved by remedies with a seda-
tive and tonic effect such as bro-
mides or electricity, without specific
reference to the stomach
patients have the greatest distress
when the stomach is empty and
even overeating is a relief
mental or physical labor on an empty
stomach may cause pain in the
eyes, head, stomach or general ner-
vous distress all over the body
patients may go for some time on
unregulated diet but suddenly ordi-
nary food will cause distress, flatu-
lence, nausea, diarrhea

12 *Special idiosyncrasies in regard to
food, medicine and external irri-
tants*

patients desire stimulants and nar-
cotics for relief of the exhaustion
but one sign of the neurasthenia is
the inability to bear even those
to which the patients are accus-
tomed (tobacco, coffee, tea, alco-
hol)
some who ordinarily can stand only
small amounts of alcohol when de-
pressed can drink quantities

may have an idiosyncrasy for hot or
cold water

opium is apt to aggravate insomnia

II *Symptoms of Cerebrasthenia* (indicate
that the exhaustion is chiefly cere-
bral)

Tenderness of the scalp

Tenderness of the teeth with whitish
appearance of the gums

Yawning

Disorders of the special senses

changes in "expression" of the eyes
pain and aching in the ears due to
hyperesthesia of auditory nerve
subjective odors and tastes (phos-
phorus or ozone, bitter and sour)
atonic voice (resembles that of
deaf person but can be distin-
guished)

Deficient thirst and capacity for as-
similating fluids

Congestion of the conjunctiva (neur-
asthenic asthenopia or irritable
eye)

the effect of nervous irritation, and
comes and goes under exciting
causes

resembles cold in the eye or the
congestion from drinking
bad in the morning but disappears
at night

*In cerebrasthenia muscular exercise
can be well borne and is frequently
desired and sought*

III *Symptoms of Myelasthenia* (indicate
that the spinal cord is chiefly af-
fected)

Tenderness and pain in any part of
the spine from nape of the neck to
the tip of the coccyx

Creeping chills up and down spine

Convulsive movements of the arm
leg or whole body especially on
falling to sleep

Fidgetiness

one of the myriad results of spinal
irritation

hand and arm may be so "nervous"
patient cannot continue writing
when legs are affected he must
get up and walk even though ex-
ertion aggravates the asthenia

Dilated pupils

there may be sudden and frequent alterations, or temporary inequalities with one contracted and one dilated

One or both ears, hands or feet may be cold to touch even in warm weather, in a hot room, or when thickly wrapped

Heaviness and stiffness of the muscles

Fleeting neuralgias and shooting pains simulating those of ataxia but probably milder

Vague aching in the loins and limbs simulating rheumatism which may follow over-exertion or come on without apparent cause

Pain in the feet

burning and tenderness at the bottoms of the feet

may be only painful spots

in both neurasthenia and ataxia it comes from the spinal cord but in the latter organic, and in the former functional, disease is signified

in some cases may be reflected from the stomach and genital apparatus

Physical exertion requiring either the upper or lower limbs, especially walking and standing, cannot be borne and if persisted in may aggravate the condition

Symptoms showing exhaustion of the upper part of the spinal cord
pain and heaviness in the back of the head

muscae volitantes or floating specks before the eyes

clamminess of the extremities

general or local itching with no change in appearance of the skin

Neurasthenic patients complain that they have "so many symptoms" but the varying and multitudinous symptoms are largely the result of reflex irritations transmitted not only through the ordinary motor and sensory nerves, but also through the sympathetic system and vasomotor nerves. For this reason neurasthenia must be differentiated from the organic disease which it simulates

in many instances, although usually the symptoms of organic disease are fixed and stable while those of neurasthenia appear, disappear and reappear without clear cause

Ballet¹⁰ states that whatever be the clinical form which neurasthenia assumes, a peculiar mental state always accompanies it. The patient is subject to hypochondria and is haunted with thoughts of cancer of the stomach, softening of the brain, disease of the spinal cord or heart disease, according to the location of his distress. His memory fails him, he is disturbed at the sight of a stranger among his usual associates, is timid, fearful, impressionable and pessimistic. However, the neurasthenic is usually quiet, introspective and retires into himself, he does not show the irritability and egotism which is characteristic of the neurotic. Because of the morbid and introspective state of mind and the complicated reflex action throughout the entire body, innumerable "vicious circles" are established with psychic and physical disorders acting and reacting one on the other.¹⁷ The subjects may be fat, hearty and even vigorous looking men who deplore the complete change which has taken place in their personality, the fears and obsessions, the digestive and circulatory derangements, the weakness of will and overwhelming lassitude which all unite to give them a feeling of impotence (Ballet). Beard reports the case of a clergyman of middle age who had suffered from neurasthenia for many years following heat prostration. Among numerous other symptoms were attacks of depression lasting about a day and brought on by any exhausting or disturbing influence. The attacks were usually ushered in

by a feeling of mental exaltation, followed by diplopia and a regular series of minor nervous phenomena

The asthenia of neurasthenia is usually subjective and often presents the peculiarity of localizing in a certain muscular group. Where there is spinal exhaustion and the asthenia is confined to the lower extremities, the patients, usually neurasthenic women, finding they are unable to walk or even to stand believe they are paralyzed and refuse to leave their bed or couch. These individuals may unnecessarily remain helpless invalids for the rest of their lives. Only about 50 per cent of the cases of neurasthenia are cured.

With reference to a constitutional neurasthenia, Ballet believes that where there is an inherited nervous weakness of infectious or other origin, or a neuro-arthritis constitution, the subjects are on the verge of neurasthenia from birth since their nervous system tires even in the course of a regular and quiet life. Londe finds that in such cases there is a failure to adapt the psychic to the somatic life, or a failure to adapt the individual to the exterior world, to his social milieu, to his occupations. However, cases of true neurasthenia among this group of subjects are probably rare.

PSYCHASTHENIA

Often, after the development of a well-marked neurasthenia, new and more serious troubles of a psychopathic order will manifest themselves. Aschaffenberg¹⁸ finds that the stronger the body, the more clearly the clinical picture of neurasthenia will appear, and the more serious and continuous

the damaging influences the more severe will be the exhaustion of the forces, but, even so, in such cases the neurasthenia does not progress beyond itself and the organism remains free from the many and varied psychopathic complications which may develop in a weaker subject or where the nervous diathesis predominates. In such cases, neurasthenia may be but the forerunner of insanity, in the form of melancholia. Hysteria is rare although some hysterical symptoms may be present. Benon lists the possible psychic sequelae of neurasthenia as follows:

- A disposition to anger, unnerving and irritability
- Mental confusion (confusion, usually transitory, in perceptions with no recognition of persons, places or things)
- The obsession phobias
- Alcoholism
- Amnesia
- Hypochondria
- Periodic psychosis
- Mania
- Various forms of delirium (persecution, etc.)
- Melancholia
- Dementia praecox (in young subjects)

Aschaffenberg defines the psychasthenic states as the *slight* forms of psychic disorder which belong to the borderland between mental health and disease, the patients are neither insane nor quite sane¹⁹⁻²³. Janet²⁴ has collected and grouped under the heading of psychasthenia all the functional psychological states, the absurd fixed ideas, the useless and ridiculous manias and unjustified fears and obsessions, which appear and disappear in the form of attacks or crises with

more or less normal periods intervening Janet believes that such mental troubles have a relationship to the regularity of intracephalic pressure and vasomotor troubles, to digestive disorders from gastrointestinal atony, to urinary hypoacidity, cardiac weakness and vascular hypotension, to troubles of the secretions and of genital function

Burr²⁵ considered that the term "psychasthenia" should be reserved for the state of pure mental exhaustion from intellectual overwork and excessive nervous strain (cerebrasthenia) and that neurasthenia is the more or less constitutional state described above by Ballet and Londe

NEUROCIRCULATORY ASTHENIA

The condition variously known as neurocirculatory asthenia,²⁶⁻²⁸ neurocirculatory myasthenia,²⁹ effort syndrome,³⁰ irritable heart,³¹ soldier's heart, disordered action of the heart,³² etc., has been brought to the attention of the medical profession during the different wars in this country and in Europe when the excitement, fear and emotional strain of examination for the army or the exertion of actual service have made active an often latent instability or weakness, which is evidenced principally by disordered heart action. The heart, itself, shows no lesion either of the muscle or of the valves, and patients with true heart disease do not present the syndrome. The symptoms of neurocirculatory asthenia may be listed as follows, stressing again that the symptoms vary in prominence and are not all present in the same individual:

TABLE IV

SYMPTOMS OF NEUROCIRCULATORY ASTHENIA

- 1 Easy fatigue and lassitude
 - 2 Disordered heart action
 - tachycardia
 - forcible beating
 - palpitation
 - arrhythmias
 - systolic apical murmur in 85 per cent
 - 3 High systolic pressure
 - after exercise the systolic pressure rises and the diastolic pressure may drop to zero (Robey and Boas)
 - 4 Left chest pain and soreness of the skin over the left chest
 - 5 Defective capillary circulation
 - 6 Cyanosis of the hands and lips
 - 7 Breathlessness on exertion
 - may be due to
 - (a) reduced vital capacity of the lungs
 - (b) irritable nervous system
 - (c) acid reaction of the blood
- With the addition of only small quantities of CO₂ or lactic acid produced by exertion, the blood due to a deficiency of certain blood constituents becomes more acid than normal and this is immediately signaled by breathlessness, the respiratory center being extraordinarily sensitive to the blood reaction (Lewis)
- 8 Giddiness, dizziness on lowering the head, or vertigo
 - 9 Fainting with or without loss of consciousness
 - 10 Sweating
 - It is common to see these patients shaking with cold and perspiring profusely from the armpits
 - 11 Increased susceptibility to cold and changes in the weather
 - 12 Exaggerated reflexes
 - 13 Tremor
 - 14 Headache
 - 15 Blushing and pallor
 - 16 Irritability of temper
 - 17 Inability to fix attention
 - 18 Sleeplessness or disturbed sleep with bad dreams
 - 19 Aphony

Examination of these patients has shown that in at least 50 per cent there is physical weakness and an inherent nervous instability, for which there is no cure, in the army they are classed as a group of "substandard" men and in civil life they represent the various constitutionally inferior individuals usually with family histories of neurotic and psychopathic disorders. Where the condition was not constitutional, it was found to be due to the too-severe drilling and the hardships of army life, or to be of infectious origin. Many of the subjects showed evidences of a low-grade infection from diseased tonsils and teeth, intestinal infections, incipient or healing tuberculosis, etc., or the symptoms might have dated from an acute infection such as rheumatism, typhoid, dysentery, pneumonia, malaria. Where the condition was attributed to the *rigors of war and army life, no definite constitutional weakness could be determined* but the individuals had been recruited from clerks and office workers, students, waiters, etc., and could not adapt themselves to the new environment.

Lewis explains that when a healthy man takes sufficiently strenuous and prolonged exercise, he experiences a certain well-defined set of symptoms, such as breathlessness increasing in intensity, consciousness of the heart action with elevation of the pulse rate, giddiness or faintness, fatigue, aching over the precordial region and later more violent and widespread pain, and finally exhaustion, and the only difference between this physiological state and the condition known as neurocirculatory asthenia is merely that in

the latter a much smaller amount of effort is required to produce the syndrome.

It would be our opinion that here there is no trace of asthenia but rather an extreme instability of the sympathetic nervous system. Rothschild emphasizes that neurocirculatory asthenia cannot be regarded as a disease entity and that "the name is purely descriptive of the major symptoms, which are referable to the nervous and circulatory systems and associated with an increased susceptibility to fatigue." Crile³³ in a recent paper states that in making a diagnosis, all the cases of mental or psychic origin and all those in which there is infection or a heart lesion should be ruled out, and then if, in the absence of all these, there is extreme cardiac instability, if the pupils dilate as the result of pressure on the epigastrium, if tremors, sweating and cold hands and feet are present, a diagnosis of neurocirculatory asthenia may safely be made. He believes this is a pathological state in which there is an excessive stimulation of the adrenal-sympathetic system and advocates denervation of the glands as a remedy. Simici, Popesco and Sandulesco³⁴ concluded that in many of the cases of permanent cardiac instability there is a latent hyperthyroidism.

HYPOSTHENIA

Mercier³⁵ describes hyposthenia as a state intermediary between "normal" and a complete, well-characterized asthenia. The "hyposthenics" are the patients who are always in a state of hypovitality, who fatigue easily and rapidly, who have no courage, no interests, no amusements. Their diges-

tion is poor, they sleep badly. On examination, no determining affection can be found but they show muscular hypotony and visceroptosis, hypocombustion with a decreased basal metabolic rate, hypothermia and arterial hypotension. The hyposthenic syndrome might be described as general hypofunction, the organism is regulated at a point "between physiology and pathology" and it is difficult to decide where the deficiency commences.

Very often these individuals are tall and spare with sagging abdominal viscera, low resistance and a caliber of mind which makes them unacceptable as companions, and it is this type which is usually thought of as the "hyposthenic habitus". However, there are many tall, spare persons with elongated and ptotic viscera who have good digestion, a healthy mental outlook, emotional stability and a fund of nervous energy beyond the normal. Also, Ballet describes a "precocious neurasthenia", which makes its appearance at puberty or a little later, and is found in patients who are notably taller than the average and whose girth of chest and volume of muscles are not proportionate to their height. These *neurasthenics* are almost always of the male sex, they are long and lean, and their nervous system is endowed with excessive fragility and yields to the slightest shock.

This exaggerated growth of the long bones at puberty is one of the most pronounced manifestations of thyroid over-activity and since a fairly large percentage of these patients show signs of thyroid dysfunction, it is a question whether some are not suffering from hyperthyroidism rather than from either asthenia or any fundamental nervous trouble. In normal in-

dividuals of the same body type, it might be supposed that the thyroid had quickly returned to normal function.

The two terms, hyposthenia and neurasthenia, have come to have a very broad meaning and are used to describe almost any kind of constitutionally inadequate or neurotic individuals³⁶⁻³⁹. There is a nondescript group of patients who are passed around from physician to physician and on to surgeons and various specialists. By the time they are finished, they have had their appendices and gallbladders removed, have had a partial or total thyroidectomy, have probably been to a sanatorium for treatment of tuberculosis or have had treatment for peptic ulcer. No therapeutic measure seems to be of avail and the patients after years of treatment are classed as either hyposthenics or neurasthenics, depending upon the mental attitude, and, one hopes, are given a logical treatment of support and encouragement. Every clinic has its quota of these cases and the physician does well if he can avoid adding to the patient's distress.

It seems that most of these patients are not necessarily asthenic or neurasthenic but are what Kerley speaks of as "50 and 75 per cent individuals"; they are never able to adapt themselves to their environment and are never equal to what is required of a normal person. The histories in these cases show, for instance, that the father died at 47 of pulmonary tuberculosis, the mother died at 60 of Bright's disease and four sisters and brothers died in infancy. Deschamps remarks that every infant is born with a certain amount of "initial force" which remains the distinctive mark of the individual, it is

his biological destiny. It is probably because the terms hyposthenia and neurasthenia are used so indiscriminately that the real condition of asthenia is so little recognized.

ETIOLOGY

Deschamps⁴⁰ states that the sthenogenic function comprehends two principal factors. The production and the distribution of energy. Energy is furnished by the metabolism and the secretions, and the nervous system has the function of organizing the use of the force created by favoring or inhibiting its distribution. The fact that, on the basis of exactly the same physiological state, voluntary and involuntary movements and ideation may vary in rapidity, force and duration, would seem to imply a variability in the transmission of energy. The degree of asthenia or hypersthenia might be referred to as the neurosthenic state, in contrast to the state of physical strength depending upon size and development, nutrition, hygiene, etc. Tastevin says that the organism is dependent upon this neurosthenic function for the power to execute any voluntary movement or for the power to think. The will, the perceptions and the special senses remain intact, but the asthenic lacks the actual power to think or to act so there must be an inhibition somewhere between the ideation and the transmission of the nervous influx which is necessary for the production of muscular contractions or to assemble ideas. In hypersthenia the influx is excessive, ideation is quick and lively with a facility of expression, the individual has a feeling of confidence and self reliance, also, there is a desire for muscular ac-

tivity and all movements are executed with ease and rapidity. Since the nerve centers are the accumulators, transformers and distributors of all energy produced by the unceasing process of metabolism, it follows that in asthenia it is the nerve centers which are deficient.

It has been suggested that anything which precipitates a disturbance of sympathetic function will cause asthenia. The sympathetic system is responsible for automatic or involuntary movements, it is the system which innervates the smooth muscles and the glands. Cannon^{41, 42} states that the neurone relations seem devised for widespread diffusion of nervous impulses, the extensiveness of the distribution of the fibers is one of the most prominent characteristics of the sympathetic, in contrast to the parasympathetic, division of the vegetative system. Also, the connection of single preganglionic fibers with numerous outlying neurones does not seem to be arranged for specific effects in this or that particular region. The sympathetic is in close relation with the cardiovascular, the digestive, and genito-urinary systems. The muscles of respiration are striated muscles and have no connection with the sympathetic but those surrounding the bronchioles are smooth and are subject to vegetative control. The fibers concerned in the maintenance of arterial pressure, the heart rate, the size of the pupil, etc. are constantly discharging while others such as those leading to the sweat glands are normally at rest, all parts are capable of reflex excitation and inhibition (Bard).

The results of excitation of the two divisions of the vegetative system might be listed as follows:

TABLE V

VAGOTONIA	SYMPATHETICOTONIA
myosis and ciliary contraction	dilation of the pupils
increased secretion of saliva	exophthalmia
contraction of bronchioles	dilation of bronchioles
bradycardia	tachycardia
hyper- and at times retro-peristalsis	inhibition of peristaltic movements
gastric hypermotility and hypersecretion	inhibition of gastric secretion
vomiting	relaxation of stomach and intestines
constipation	diarrhea
bladder evacuation	bladder retention
	<i>extreme weakness</i>
	tremors in the skeletal muscles
	syncope
	"goose-flesh"
	erection of hair
	hyperhidrosis
	from forehead
	from axilla
	from palms and plantar surfaces
	constriction of the arteries
	pallor
	cold extremities
	various ischemias
	liberation of sugar from the liver
may be sequence of acidosis, elevation of vagal tonus and vaso-dilation	may be sequence of alkalosis, elevation of sympathetic tonus and vaso-constriction
high blood potassium	high blood calcium
high blood phosphorus	low blood phosphorus
vagotonia increased by pilocarpine	sympathicotonia increased by adrenalin
vagotonia decreased by atropine	

When the sympathetic division of the vegetative system is unduly excited, a definite set of symptoms will be produced, chief among which are *weakness* with a loss of the feeling of stability and possibly tremulousness, tachycardia, sweating, diarrhea, and vascular contractions causing pallor or localized ischemias

In the nervous hierarchy, the sympathetic is regarded as the connecting link by which cerebral activities act on the viscera. Bard⁴³ believes that the marked tendency of the sympathetic to react vigorously and as a whole under conditions of stress implies control of the system by a central mechanism. Also, all sympathetic discharges can be broken by central inhibition or augmented by central excitation.

The vasomotor center is situated in

the bulb. Bard states it is certain that a narrowly localized bulbar mechanism makes a definite connection with the sympathetic outflow to the arterioles. Experimental work indicates that there is a single cardiac center in the bulb, controlling and coordinating vagal and sympathetic discharges to the heart. The vasoconstrictor, vasodilator, cardioaccelerator, and cardioinhibitory mechanisms are closely related physiologically and anatomically they appear

to be closely juxtaposed in the medulla oblongata. Deschamps states that the bulb has been proven to be the most sensitive and easily affected of the nervous centers and that asthenia is especially a bulbar state. In asthenia and in neurasthenia, there may be constant alternating of vascular contraction and dilation and extreme instability of the pulse with variations of cardiac rhythm merely on moving. A low blood pressure is a constant finding in asthenia but it is also common in hypersthenia. We have observed one of the most truly hypersthenic normal individuals that could be found whose systolic pressure during the most active period of his career was consistently around 100.

Bard finds, however, that there is no indication of a localized bulbar center for such sympathetic processes as the secretion of sweat, the erection of hair, inhibition of gastrointestinal motility and dilation of the pupils.

In the organization of the central nervous system, each of the lower mechanisms is influenced or controlled from above, the higher levels may not be necessary for their function but they are able to influence it. Superimposed on the bulbospinal mechanisms controlling the sympathetic is a mechanism located at the base of the diencephalon which is capable of causing a simultaneous discharge over the entire sympathetic system and which is activated in times of stress and emergency (Bard). Huber and Crosby⁴⁴ state that the diencephalon is a primary center involved in various types of emotional expression. The diencephalon is divided into the hypothalamus, the epithalamus, and the dorsal

and ventral thalamus. Various researches indicate that the thalamus is closely linked with the whole range of pleasurable and painful qualities, irritation or injury of the region may change the whole affective attitude of a person. Pain apparently comes into consciousness in the thalamus. The diencephalon also appears to contain the neural mechanism essential for the maintenance of body temperature and it is significant that exposure to cold and strong emotional excitement call forth similar bodily changes by activation of the sympathetic through stimulation of the diencephalon. Pain and disturbing emotions are two of the most important of the dysthenizing factors. Also hypothermia and increased susceptibility to cold are common findings in asthenia and changes in the affective attitude of the subjects are frequent. There is much to suggest that it may be in the diencephalon that the mechanism regulating the neurosthenic function is situated.

Londe finds that among maladies of the nervous system it is those of the cerebellum which are most often accompanied by asthenia and he believes that asthenia is a cerebellar-sympathetic phenomenon.

Danielopolu⁴⁵, after 20 years' research, states that the vegetative system possesses an automatic tone which is maintained by the action of the electrolytes, the secretions and the various substances produced by the vegetative organs themselves. Normally these are furnished in such proportions that there results an ideal milieu for the maintenance of functional equilibrium with the two physiologically antagonistic groups, the sympathetic and para-

sympathetic, in a state of permanent and equal excitation. But over the whole system reign the encephalic coordinating centers and the cerebral cortex, which has an incontestable influence on the organs with vegetative innervation. The cardinal factor in asthenia is the actual inhibition of nervous influx necessary for voluntary movements and for the process of thought, in hypersthenia the ease and rapidity of all voluntary movements and the quick ideation are the predominant characteristics. It might be logical to suppose, therefore, that the dynamic state is controlled at the highest level with various reflex influences on the lower mechanisms, but the reflex action between the different regions is so strong that it is difficult to determine just where the inhibition occurs.

Regarding the constitutional states, Pende⁴⁶, Garrod⁴⁷, Draper⁴⁸, *et al*, like to speak of asthenic, hyposthenic and hypersthenic types which seem to have reference mostly to the endocrine glands and to embryonic development. The asthenic type is supposed to result from such factors as an overdeveloped lymph system, too much stroma for the parenchyma, or defects in the chromosomes; Deschamps believes that what is transmitted is a defective structure of the protoplasm and a certain physicochemical aptitude. However, there are all sorts of constitutional deficiencies and it would seem that a condition could be regarded as constitutional asthenia only when the deficiency is in the nerve center responsible for regulating the neurosthenic state. Londe states that when the asthenia is constitutional it may mani-

fest itself from birth in the slowness and rarity of the child's movements, the difficulty even of swallowing and in the cry. Since clinical study fails to associate the asthenia with any cause whatever, it must be congenital.

DIFFERENTIAL DIAGNOSIS

The condition of asthenia is to be distinguished from such states as atony, apathy, lethargy or melancholia.

Asthenia is a *dynamic* state, atony, or the abolition of muscular tone, is a *static* state of the muscles. The sthenia or dynamism is the active phenomenon of the sthenogenic function and the tonus is the passive or automatic phenomenon. Muscular tone, which is not the same as the reflex, is a state of automatic contractility, a state of tension (Deschamps). There may be atony due to lack of exercise, to stretching and sagging of the visceral ligaments and muscles with a consequent elongation and ptosis of the organs, or after pregnancy with the relaxation and loss of tone of the entire abdominal musculature. This state of atony, however, need not be accompanied by any degree of asthenia.

Tastevin explains that apathy is a state of *activity* which is generally constitutional and in some respects resembles asthenia. When the apathetics speak, their voice is slow and relatively low; their gestures are slow. Their motive reactions of emotional origin are restrained; where a normal person will laugh, the apathetic will smile. Apathy differs from asthenia in the fundamental respect that while the asthenic is rapidly exhausted when he moves, the apathetic can accomplish as intense and as prolonged move-

ments as a normal person. On the one hand, it is a question of the supply of nervous matter, and the influx is soon exhausted, on the other hand, because of a constitutional nervous disposition, the expenditure is made slowly but may be long continued.

It might be said that some of the toxemias and metabolic states produce lethargy rather than asthenia.

Objective asthenia, especially where the patient has become depressed over his inability to regain his normal state is often wrongly diagnosed as melancholia but melancholia is a distinct and well-defined mental disorder. In the second case described by Tastevin, the patient had been subject to attacks of asthenia lasting 6 to 9 months for over 40 years and at the age of 74, there was no weakening of her intelligence. Yet melancholia may be complicated by asthenia, and asthenia occurring in a weak organism may develop into melancholia.

In table I is given a list of the conditions and states which the various authors believe can produce asthenia. However, as Londe states, almost any lesion or even a slight and localized functional trouble may diminish muscular energy, and it is necessary to distinguish between those causing a true asthenia, those which by disturbing the metabolic processes produce a state of lethargy, and those which disturb the equilibrium of the vegetative nervous system. The problem is a complex one and the intricacy of body structure and function and the innumerable possible complications of disease make it difficult at times to decide just what is asthenia and what is not. For instance, included in the list are hypoglycemia

and diabetes. Hypoglycemia may be due to hepatic disorders, to hyperthyroidism, to hyperinsulinism from various causes, but among the most notable symptoms of hypoglycemia are mental confusion, epileptiform attacks, stupor, mania, etc. The manifestations of a moderate lowering of the blood sugar level are⁴⁰⁻⁵⁴

weakness
fatigability
pallor
sweating
restlessness
rapid pulse
muscular twitching
dilation of pupils
disturbed sleep
anxiety
ravenous hunger

Cannon, McIver and Bliss⁵⁵ explain that it is the sympathetic fibers which release glycogen from the liver and this reaction of sympathetic excitation is due to increased adrenal discharge in response to nervous impulses and is another remarkable example of automatic adjustments within the organism when there is a disturbance endangering its equilibrium. The mechanism protecting the body from hypoglycemia probably operates in two stages. A primary stage in which sympathetic activity with adrenal secretion occurs to mobilize sugar from the liver, and, if this proves inadequate, a secondary stage in which the activities of the first stage are intensified and augmented in convulsive seizures.

Diabetics complain of both weakness and depression yet the weakness may well be due to the inadequate diet or to the reaction of the sympathetic system to the hyperglycemia and the depression may be the result of a collec-

tion of partly metabolized products which will lead eventually to acidosis and coma. However, it is claimed, also, that the auto-intoxication of diabetes may act as a dysthenizing agent, in which case the asthenia should be distinguished from the other forms of weakness occurring during the course of the disease from other causes.

Colibacillosis is mentioned as a dysthenizing agent but Goiffon⁵⁶ has found cases where the colibacillosis as well as the asthenia (?) seemed to be the result of an underlying alkalosis.

Many authors believe that it is disturbances of the acid-base equilibrium acting on the vegetative system which causes asthenia, although there seems to be some confusion as to whether a predominating acidity or alkalinity causes vagotonia or sympathicotonia⁵⁷⁻⁶⁰. Goiffon finds that, in reality, alkalosis and acidosis are but two deviations of the normal equilibrium which, after reaching a certain point, produce analogous troubles. He believes, however, that the rôle of alkalosis in pathology is vast and lists the general findings about as follows:

TABLE VI

ALKALOSIS

lassitude (is common)
muscular weakness
drowsiness
loss of memory
headache with a tendency to vertigo
tachycardia
low arterial pressure
respiration is either slow or superficial,
ventilation is diminished, and the
pressure of carbonic acid is raised
digestive troubles are constant
hepatic insufficiency is very frequent
constipation with or without attacks of
diarrhea

sometimes there exists a diarrhea of fermentation with very acid stools and a relatively low level of total organic acids

urinary organic acids may reach three or four times the normal when the urine becomes alkaline, showing imperfect combustions

blood uric acid, lactic acid and oxalic acid are augmented

phosphaturia and alkalosis are almost always associated

a vegetable diet aggravates the condition by further alkalinizing the blood

Drouet⁶¹ in a discussion of the relation between the acid-base equilibrium and the equilibrium of the vegetative system, states that "anxiety" has long been catalogued as a manifestation of sympathicotonia and that the individuals show a permanent ionic alkalosis and a permanent hypoacidity of the urine, increased during the attacks. Guillaume (cited by Drouet) calls "anxiety" the morbid psychic tendency toward which the sympathetotonic inclines. Drouet states also that in epileptics there exists an habitual alkalosis even reaching a blood pH of 7.70, the number and intensity of the crises seem to vary with the alkalosis and in the intervals between the attacks the pH returns to normal. He cites Walther and Guillaume as having demonstrated that an epileptiform attack is the consequence of encephalic ischemia due to an energetic constriction of the arteries of the brain, that is, to a vascular sympathicotonia which extends also to the arteries of the cutaneous tissue causing pallor and to every arterial tree causing an elevation of the arterial tension before an attack and at its beginning. He believes that ophthalmic migraine is characterized by

sympatheticotonia in the form of arterial spasm and by blood alkalosis

Montassut and Delaville believe that the "constitutionally depressed" have a tendency toward a chronic alkalosis and that the inhibitions to which they are subject yield only after a certain amount of muscular activity has caused acidifying of the blood. Gorffon believes that the type of individual described above as the "hyposthenic" is really possessed of an alkaline diathesis or a predisposition to a permanent and constant alkalosis. Meyer⁶² believes that an abnormal alkalinity of the blood serum is the *primary* lesion in cancer which, in conjunction with certain other factors, favors the appearance of the cancer wherever a chronic local irritation is present. He reports cases of inoperable malignant tumor with metastases which were, to all appearances, cured by inducing acidosis and by keeping the pH at the normal level with hydrochloric acid and inhalations of O_2 - CO_2 whenever a recurrence seemed likely.

The investigators who are interested in hypoglycemia say this is a very common finding and that wherever there is a state of notable weakness and easy fatigability a low blood sugar should be suspected. Those interested in alkalosis believe that in all states of slowed up energy, the trouble may be attributed to alkalosis. Likewise, those studying the rôle of the adrenals in the body economy, state that asthenia is the result of depleted function of the adrenal cortex. It is assumed that Crile's theory of adrenal-sympathetic overactivity as the cause of neurocirculatory asthenia refers to the adrenal medulla and an increased secretion of

adrenalin. But in Addison's disease, due to cortical deficiency, an entirely different state is produced which is also spoken of as asthenia.

TABLE VII

ADRENAL CORTX DEFICIENCY

general languor and weakness (asthenia is the cardinal symptom)
 low blood pressure
 pigmentation of the skin due to abnormal deposits of melanin, the normal cutaneous pigment
 gastrointestinal disturbances of varying severity
 vomiting is constant and sometimes uncontrollable
 anorexia
 nausea
 aversion to fat
 constipation
 acute gastric ulcers
 epigastric pain
 abdominal wall may be rigid and tender
 simulating peritonitis
 loss of weight but it is noted that in a large percentage of cases the patients are overweight at the time of the first symptoms
 weak heart action
 vertigo and faintness on arising from bed
 hypothermia or fever
 nervous symptoms are numerous and prominent
 mental irritability
 restlessness
 areas of hyperesthesia
 hallucinations
 actual delirium and even acute mania
 convulsions
 coma
 nervous symptoms may be due to either anoxemia or to degenerative changes in the central nervous system
 cortical deficiency is caused by two principal pathological lesions, tuberculosis and simple atrophy, pigmentation is more often associated with atrophy

In this syndrome there are very few of the sympathetic symptoms which are so prominent in neurocirculatory asthe-

nia and in hypoglycemia while the vomiting suggests vagal predominance. The two significant findings from the standpoint of asthenia are the fatigue and the low blood pressure. Yet almost without exception, by the time these symptoms appear the adrenal tissue, of both medulla and cortex, has so degenerated that the patient survives only a few months at the most, while asthenia even of the objective type may exist for years and it is specifically stated that at autopsy no trace is left on the organism. In Addison's disease degenerative changes in the central nervous system are often noted in addition to those in the adrenal glands. Rogoff and Stewart^{10,61} believe that the low blood pressure in Addison's disease is probably a manifestation of intoxication. Rowntree⁶⁴ also states that there is much about the terminal picture in Addison's disease to suggest intoxication, affecting chiefly the central nervous system. Certain signs of intoxication were apparent in a series of seven cases reported by Hartman and his associates⁶⁵; laboratory examination showed a blood urea extending from 33 to 130 milligrams in five of the seven cases, and in two there was a leukocytosis of 14,000 and 21,600 respectively. The basal metabolic rate showed from 9 to 28 per cent decrease.

If it be true that the adrenal cortex is largely concerned in the destruction of products of metabolism and bacterial toxins and in furthering oxidation generally, any symptoms of intoxication following cortical deficiency are easily understood. But the point of interest in this discussion is whether this is a state of intoxication which is

to be differentiated from asthenia or whether the intoxication acts as one of the dysthenizing agents. In this connection, reference might be made to an article by Porritt⁶⁶ describing a type of lead poisoning in which the usual symptoms of plumbism are not exhibited. In these cases there is a slow, insidious saturation of the system over a long period of time by infinitesimal doses of lead contained, usually, in drinking water which is piped through lead pipes. The chief complaint of these patients is that they are "always tired." Porritt states that a strange *lethargy* creeps over the sufferer; he loses interest in life and feels a "weariness of flesh and brain." As the condition progresses, he becomes gloomy and taciturn; instead of joining in conversation with relatives and friends he sits silent and apathetic as if overcome by thoughts too melancholy to utter. His bowels are constipated and stubborn, he derives no satisfaction from his food and perhaps has abdominal discomfort which he puts down to indigestion. Sleep brings welcome respite but he gets up tired and weary in the morning. In neurotic females, emotional outbursts with flatulency and abdominal pain, may punctuate the melancholy. Lead is quickly excreted and the symptoms disappear when the cause has been removed.

The author states that in such cases the subject prefers sitting by the fire to making an effort of any sort yet when he forces himself through his tasks he finds no diminution of brain or bodily power. Feinblatt⁶⁷ in reporting a case of Addison's disease fol-

lowing tuberculosis of the vertebrae states that though the symptomatic asthenia was great, the power of the voluntary muscles to do work was normal. Cancer is mentioned in the table as one of the dysthenizing factors, but since all cancers do not cause asthenia it may be that it is the type of malignancy developing in a medium of chronic alkalosis which causes, not asthenia, but a similar state of intoxication. Such conditions not only poison the whole nervous system but in addition alter the internal chemistry and even the structure of the protoplasm of the cells.

Deschamps explains that there are three distinct conditions: (1) *Fatigue* which is the result of actual tiring, (2) *fatigability* which is anterior to fatigue and is a lowered work-tolerance, and (3) a *sensation of fatigue* which may exist independent of both fatigue and fatigability. A subject may be asthenic without experiencing the sensation of fatigue if he does not expend his capital of energy or he may experience the sensation of fatigue without being either fatigued or asthenic.

The numerous individuals who are called "lazy" undoubtedly experience the sensation of fatigue. Fuller⁶⁸ remarks that activity creates the capacity for further activity and that laziness is a purely mental condition with material physical consequences. It is the rapid distribution of oxygen to the tissues which constitutes healthy organic life. In anemia, where the reduced oxygen supply to the tissues is due to the diminished hemoglobin or erythrocyte count, a "lack of force" is also noted.

TABLE VIII

ANEMIA

easy fatigue and general lack of physical energy
 inability to stand prolonged mental and physical strain
 patients are never very ill and never very well
 they become breathless on the slightest exertion
 are nervous and worry over trifles
 there is impaired nutrition and weakened action of the heart muscle
 cold, and perhaps moist and clammy, hands and feet
 a tendency to chilblains
 gastritis is common in all forms of anemia and, in the extreme type, gastric ulcer
 there is a lowered resistance to even ordinary infections

All infections and intoxications may cause either anemia⁶⁹ or the syndrome of sympathetic instability so in the presence of an infective process, it will be a question of differentiating these two forms of weakness from asthenia.

If one wishes to assume that all conditions causing a lack of force or strength should be considered "asthenia" the problem might be solved by stating, as does Deschamps, that there are asthenias of production and asthenias of distribution. The asthenias of production would include all the states of weakness, fatigue, depression and lowered resistance caused by the various physicochemical disturbances, glandular disorders, malnutrition, anemia, toxi-infections or any other factors which interfere with metabolism and the production of energy. Asthenias of production would include also all the constitutional states the 50 and 75 per cent individuals, where the organism is not equipped to produce sufficient energy.

The same author uses a slightly different classification as follows

Asthenias of insufficiency where there is an inadequate supply of energy produced
 Asthenias of exhaustion where the supply has been exhausted as in convalescence or perhaps in neurasthenia

Asthenias of inhibition where there is an obstacle in the nervous system which prevents the transmission of energy

Deschamps states, however, that to call every diminution of energy "asthenia" is a misinterpretation and most of the other authors agree that asthenia is strictly autonomous and that the term should be confined to the "asthenias of inhibition" where there is an arrest of the transmission of energy

TREATMENT

Except in the constitutional cases, asthenia occurring in the absence of a definite dysthenizing agent is probably rare. Asthenia is an effect rather than a cause. Benon finds that asthenia complicates a great number of disease states, that ordinarily it is of neither diagnostic nor therapeutic interest and when the dysthenizing cause has disappeared the neurosthenic equilibrium will right itself. Deschamps says that the most curious symptomatic consequence of all types of asthenia is the impossibility for the patient to accumulate energy, regardless of all pharmacological and dietary measures.

Ballet states that in some cases the asthenia develops in the course of convalescence but most often it makes its appearance when the general health of the patient seems to have been restored. The case of intercostal neuralgia cited above is an excellent example, the patient was supposed to have recovered

from her illness when almost without warning she found herself without sufficient nervous force to make the least effort. For this type of asthenia, time and proper hygiene are the only requirements, immediate and absolute repose in bed is the primary consideration since forced effort or activity of any sort, by aggravating the asthenia, may change a temporary and unimportant complication into a state of permanent semi-invalidism. Among the numerous cases of post-influenzal asthenia, it is not unusual to observe individuals who are making an attempt to follow their normal daily routine, whether this be assuming the responsibilities of a household or engaging in business. Their friends will remark that at times they seem scarcely to have the strength to move one foot ahead of the other. In many instances, this permanent state is undoubtedly the result of a too early return to active life, with the patient forcing himself to disregard this seemingly inexplicable lack of strength. Most physicians are coming to realize the necessity for an adequate period of convalescence after acute fevers and infections, but it does not seem to be generally understood that it is because the neurosthenic function may be temporarily suppressed by the disease process.

When, as the result of forced effort during a temporary asthenia, or following trauma or emotional shock, either a permanent and incurable state or a prolonged attack of asthenia has been installed, treatment must consist mainly of the usual hygienic measures for building up the organism, with especial attention to the three fundamental principles of rest, nutrition and

elimination In these cases, because of the relaxation of the digestive tube, there may be intestinal auto-intoxication or a tendency toward alkalosis. Foci of infection in the upper respiratory tract and teeth, thorax, abdomen or pelvis or any organic trouble should be thoroughly searched for and eradicated.

It is important to determine the gastric tolerance and arrange the diet accordingly. Usually the diet will be limited to bland, easily digested foods apportioned, if necessary, into five light meals to avoid burdening the stomach too much at one time.

Physical therapy in the form of cabinet baths, pressure sprays, light massage, ultra violet rays or diathermy will prove of value in eliminating poisons and improving the circulation, and in addition will have a good psychological effect. This form of therapy is especially valuable in cases of subjective asthenia.

Deschamps believes that where the cerebral centers are deficient, there will be an associated mineral insufficiency, especially of magnesium and phosphorus, the loss of these two minerals is the surest sign of nervous deficiency. He believes the best way to reconstitute an asthenic is to give combinations of magnesium with phosphates. Phosphorus in the form of glycerophosphates is also extensively used. Small amounts of arsenic or strychnine may be given for short periods although drugs with a tonic or stimulating effect are not well tolerated as a rule.

Wakefulness and persistent insomnia are ordinarily best combated by varying combinations of tincture of

valerian, elixir triple bromides and elixir phenobarbital. The use of these drugs in equal portions and in adequate amounts is satisfactory. For extreme cases, occasional resort to codeine sulphate, gr $\frac{1}{4}$ to $\frac{1}{2}$, may be necessary once or twice in the early hours of the night to establish the somnolent state.

A certain experience with liver extract indicates that this preparation may have some substantial therapeutic value in returning the asthenic individual to his normal power although the mode of action is not known. It is our practice to recommend a tablespoonful of liquid liver extract 3 or 4 times daily for 3 to 6 weeks. Response, as indicated by an increase in the general well-being, has been noted in approximately 90 per cent of the patients so treated. While we have not yet had the opportunity of proving the efficacy of adrenal cortex hormone in the treatment of asthenia, this drug also gives promise of being valuable in certain cases. These two preparations would be expected to act by improving the general metabolism and by raising the erythrocyte count and hemoglobin and not by any direct influence on the deficient nerve center. However it is always possible that a secondary hepatic or adrenal insufficiency may have developed after an extended period in a state of objective asthenia, in which case the above remedies might have a specific effect.

Since the physicochemical state of the organism is of such significance in making a differential diagnosis and in indicating the therapeutic procedure, the required laboratory examinations should be made to detect any devia-

tions from the normal in the chemistry of the blood and urine. Where there are evidences of gastric hypoacidity, urinary hypoacidity, blood alkalosis, high blood calcium, or any other findings which suggest sympathetic predominance, vagotonic substances might be given to stimulate the parasympathetic. Various researches now being conducted indicate that posterior lobe pituitary preparations by acting on the vagus may be of value in producing gastric motility and secretion.⁷¹

Endocrine preparations such as desiccated thyroid substance, whole ovary substance, corpus luteum, adrenalin, pituitrin and the numerous modifications and combinations of these, have been tried with varying degrees of success. We have noted, especially in treating obese female patients with whole ovarian substance to which has been added 1/10 to 1/12 grain of thyroid extract, that a general increase in power has been obtained.

Ballet believes that the degree of asthenia probably has a relation to the degree of native insufficiency and where there are fundamental morphological and functional defects, a superimposed asthenia will be more exaggerated and more difficult to treat. Where pronounced psychic disturbances are present, the aid of the neurologist must be sought. In all cases of asthenia, however, the psychological background and the environment of the patient must be carefully studied from the standpoint of both diagnosis and treatment.

In the case of constitutional asthenia, the best advice would seem to be for the individuals to stop trying

to develop themselves to normal physical and nervous capacity, but to determine what their maximum abilities are and keep slightly under that limit.

TABLE IX

PRINCIPLES OF TREATMENT

- 1 *Repose (the primary and fundamental treatment for asthenia)*
Physical, intellectual and emotional forcing the patient to activity of any sort will aggravate the asthenia and cause it to become permanent.
After a more or less prolonged period of rest, muscular and mental activity may be gradually resumed, but this should not be permitted until the evolution toward cure is certain.
- 2 *Explain this peculiar form of weakness and its probable future course* not only to the patient but to his family since it is usually the relatives and friends who urge the patient to exercise and move about in order to regain his strength.
- 3 *Make a thorough search for foci of infection or organic troubles* which may be the cause of the asthenia.
- 4 *Institute the required laboratory procedures* for the detection of deviations from the normal in the physico-chemical state of the organism.
- 5 *Diet*
Give high caloric foods which are easily masticated and easily digested.
It may be necessary to increase the number of meals in order not to burden the stomach too much at one time.
In the acute stage, a milk, or milk and vegetable, diet may be temporarily indicated.
Wine may be beneficial for its mild tonic action and food value, and for raising the erythrocyte count and hemoglobin.
- 6 *Physical therapy*
Very light massage
Ultra violet light and diathermy

In the chronic cases or in the case of subjective asthenia, cabinet baths, pressure sprays, hydrotherapy, etc are of great benefit

7 Drugs

Avoid drugs in general

At times, harmless doses may be given for their psychological effect Sodium bromide is especially successful in gastric asthenia

Glycerophosphates and combinations of magnesium and phosphorus may be prescribed for the nervous deficiency

Strychnine and arsenic may be given in small doses for short periods to the calm, depressed type but will lead to aggravation in the patient with a tendency to "unnerving"

Give sedatives for insomnia

Avoid cathartics with drastic action or which cause intestinal irritation

Adrenal cortex preparations, liver extract, thyroid and ovarian substance, adrenalin, pituitrin, etc may be helpful in overcoming the asthenia

Where there is evidence of sympathetic predominance, give parasympathetic stimulants

NEURASTHENIA

In the treatment of neurasthenia, Beard states that to devote the whole attention to special and local phases such as spinal or cerebral irritation, asthenopia, oxaluria, insomnia or nervous dyspepsia can never be successful The treatment should be constitutional with special attention to local manifestations whenever they become severe but no two cases will be alike in all details Where the subject is under treatment for a long period of time, Beard advocates giving a sedative treatment one week, a tonic the second and the third to do nothing at all Sometimes suspending treatment acts as a therapeutic measure in itself

In his experience, the combination of electricity, massage, counterirritants and various sedative-tonic medications seemed to obtain the best results

In cerebrastrhenia as vigorous outdoor exercise as the patient can stand should be prescribed, in myelasthenia, especially in women, absolute rest in bed in quiet, if not darkened, rooms is necessary In digestive hygiene some need to be cautioned against overfeeding and some must be coaxed to eat more than has been their custom A milk diet may be required in some cases and in others small frequent meals of light food According to Deschamps, neurasthenics and also asthenics possess an "irritable" weakness and on the ingestion of irritating foods or medications an atonic and hypoacid stomach may quickly become hypertonic and hyperacid This irritable weakness extends to the whole organism, including the psychic apparatus

In neurasthenia the psychology of the patients is of the utmost importance Neurasthenics as a rule take a great interest in their distresses and relate their pains and symptoms in detail Beard found that the greater the amount of intellect and the less the emotional element, the better the prognosis would be

While in psychasthenia and neurocirculatory asthenia the fundamental etiology is different, nevertheless the therapeutic measures recommended above will undoubtedly have some beneficial influence in returning the individuals to a normal state

CONCLUSIONS

There appears to be a regulating neurosthenic mechanism located in the

brain which ordinarily maintains each subject in an eusthenic state. The varying degrees of sthenia, asthenia and hypersthenia may be regarded as the "neurosthenic state" of an individual in contrast to the state of physical strength dependent upon size and development, nutrition, hygiene, etc.

The neurosthenic equilibrium may be disturbed by a number of factors known as "dysthenizing agents," and an abnormal asthenia or hypersthenia may result. The most common of the dysthenizing factors are pain, emotional shocks, trauma to any part of the body with an associated total loss of consciousness, sunstroke, acute and chronic infections and intoxications such as influenza and grippe, typhoid fever, tuberculosis or malaria, streptococcic infections or food poisoning.

A differential diagnosis is of the utmost importance since muscular energy may be diminished by a number of factors and states produced which at times may be difficult to distinguish from asthenia.

Asthenia occurring as a complication of various disease states is of no especial significance and will disappear when the neurosthenic equilibrium has righted itself. Immediate and absolute repose in bed and proper hygiene are the only therapeutic requirements.

Forced effort or activity of any sort, by aggravating the asthenia, may change a temporary and unimportant complication into a state of permanent and incurable semi-invalidism, as may be observed in the innumerable post-influenzal cases where the patients, because they disregarded the asthenia and forced themselves to return too soon to an active life, have never since been able to regain their normal state.

In order to carry on, these individuals must recognize their physical and mental capacity and limit their activities at a point just under their maximum ability. Small amounts of drugs with a mild stimulating or tonic action or light wine may be given; various combinations of phosphates for the nervous deficiency, biological preparations such as liver extract, adrenal cortical hormone, ovarian, thyroid and pituitary substance, and physical therapy may be of value in overcoming the asthenia.

A study of this subject suggests that, due to the high tension living of the present age, the traumas, emotional shocks, familial and financial cares and the waves of infection which seem to spread over communities, the profession must be prepared to encounter a state of asthenia more frequently than has been the case in the past.

The Clinical Study of the Atrophic Tongue

By WILLIAM S MIDDLETON, M D, F A C P,
Madison, Wisconsin

THE bald tongue has been recognized for many years by clinicians. Its association with anemia was probably first appreciated in 1846 by Dawson¹. In 1909 William Hunter² concluded an argument for the infectious origin of the glossitic, gastric and intestinal lesions of pernicious anemia with the statement "that the most important of these signposts (glossitic) is the one which can be earliest recognized and kept in sight from the first to the last". The strength of this position was universally conceded by students of the subject, but renewed interest in and attention to the close scrutiny of the tongue in pernicious anemia arose from an appreciation of the remarkable transformation in its surface markings that attended liver therapy. Furthermore a peculiar glossitis with ultimate atrophy has been described in a wide series of clinical entities, and from this analogy a possible interrelationship is receiving increasing consideration.

This growth in the clinical importance of the subject impressed the

Presented at the San Francisco Meeting of the American College of Physicians, April 4, 1932

From the Department of Medicine, University of Wisconsin

need for an objective method of preserving the changing picture of the lingual markings. The methods pursued are recounted elsewhere³. After devious trials smoked paper, as suggested by Isaacs, Sturgis, and Smith,⁴ afforded the best results (figure 1). With practice a quite constant technic was developed; and dipped in shellac these tongue prints constitute permanent records of inestimable service in evaluating progress.

Particular interest in the present relation attaches to the study of the lingual changes in pernicious anemia. Hunter² characterized the histologic picture as of an acute and subacute inflammatory nature succeeded by degenerative and atrophic changes. Round-celled infiltration in the tissues and the walls of the blood vessels of the tongue mark the inflammatory stage, whereas atrophy of the epithelium succeeds necrosis and mucoid degeneration. In the late stage a thin fibrous sheet replaces the epithelium and deeper penetration of connective tissue into the musculature indicates the extent of the preceding inflammatory process. The actual total mass of the tongue is reduced through muscular as well as epithelial atrophy.

An advanced stage in the glossitic picture is represented by

Case I, C F, a white farmer aged 54 years, who was readmitted in the second relapse of pernicious anemia, December 1, 1931. Combined degeneration of the cord had been established on the earlier admission 4½ years previously, but the hematopoietic response to liver had been satisfactory and many of the signs of neurologic involvement had disappeared with improved strength and muscle tone, so that on his return to the farm the patient had been able to resume his work. An injury to the left ankle eight weeks prior to readmission initiated a de-

Soreness of the tongue is a common complaint among patients suffering from pernicious anemia. Yet a minority of these patients may entirely escape this subjective discomfort. Disturbances of taste are less common. Characteristic is the marginal injection of the tongue with tiny vesicles here and at the tip. These vesicles tend to rupture and leave denuded areas. The beefy redness and vesiculation are

FIG 1 Contrasting a photograph and a smoked paper print of a glossitic tongue with some degree of atrophy, taken on the same day

cline which was marked by weakness, breathlessness, paresthesias and rectal incontinence. Neglect of liver therapy was admitted. Gross evidence of cord involvement was established in absent deep tendon reflexes in the legs, loss of vibratory and position sense, ataxia in all test movements and lack of sphincter control. The tongue was completely bald and glistening. The hemoglobin registered 45 per cent and the erythrocytes 1.8 million on admission. Bronchopneumonia terminated life before liver therapy and transfusions could effect any appreciable change in the blood picture. Of particular interest in the necropsy findings was the hyperplastic bone marrow. The histologic study of the tongue (figures 2 and 3) revealed a total absence of papillae. The epithelium was thinned in areas and there was marked round-celled infiltration beneath the epithelium as well as about the smaller arterioles.

periodic and shifting in occurrence. Succeeding this stage of inflammation, denudation is the rule, but there is no relation between the severity of the inflammation and the degree of the ultimate atrophy of the papillae, nor does the former give any prognostic information as to the time of appearance of the latter. Hunter² recorded the occasional subsidence of the acute glossitic manifestations with the advance of the anemia, but added that in other cases such was not the case until atrophy of the papillae was complete. Not infrequently glossitis may antedate the anemia. In other individuals with advanced anemia the tongue changes may be insignificant.

As has been remarked, the introduction of liver into the therapy of pernicious anemia completely altered the sequence of events. Minot and Murphy⁵ noted that "the distressing tongue symptoms so characteristic of pernicious anemia usually vanished soon after liver was taken. Vesicles on the edges and tip of the tongue disappeared as did the red-streaked, raw, or beefy appearance. The sense of rawness or pain in the esophagus subsided. In a few patients who had

a pronounced disorder of the central nervous system, the disappearance of the tongue symptoms and signs was less rapid. In none of the patients who have continued the diet well have the tongue symptoms either persisted or returned. Within a few months the tongue has usually lost its shiny appearance entirely and has appeared normal."

An unusual experience is cited in Case II.

A. H., a white laborer aged 62 years, was

FIG. 2 Microscopic appearance of the glossitic tongue of Case I (low power—x 70)
(Courtesy of Dr. Gorton Ritchie)

elsewhere reported as a typical example of the recidivistic tendency of certain pernicious anemia patients under liver therapy. Beginning with his original admission, February 15, 1927, each of five successive relapses was attended by erythrocytic counts ranging from 740 thousand to 1.35 million. Not until his last two admissions of December 14, 1929, and November 20, 1930, was there the slightest evidence of neurologic involvement as manifested by a debatable obtunding of the vibratory sense in the left lower leg. On each occasion of relapse the tongue showed marked atrophy of the papillae to complete baldness. Improvement in the lingual condition anticipated the complete

blood remission. In the four periods of observation where accurate notes of the return of papillae to the tongue were made, the hemoglobin and erythrocyte figures were 60 per cent with 4.07 million, 58 per cent with 3.37 million, 55 per cent with 3.83 million, and 55 per cent with 3.65 million, respectively, at the time of papillary reappearance.

The relatively close coincidence of these figures stimulated a study of this detail, but the circumstance is apparently strictly individual and dependent upon other factors than hemoglobin

FIG. 3. Microscopic appearance of the tongue of Case I (high power— $\times 240$). Courtesy of Dr. Gorton Ritchie.)

and erythrocyte levels. In this particular instance the normal surface markings were always restored to the tongue before the blood reached a satisfactory level. Because of the patient's low mentality no accurate information was afforded of the chronologic order of glossitic symptoms and hematopoietic decline upon neglect of liver therapy. At no time during hospitalization were there evidences of acute glossitis.

The tongue prints have afforded accurate records in following the progress of the glossitic changes in pernicious anemia under liver therapy. From the evidence now available, the filiform papillae first disappear, particularly from the tip and the edges of the tongue. Thereafter the fungiform papillae are lost. The position of the circumvallate papillae renders their inclusion in tongue prints of this order impracticable, but apparently they escape gross involvement even in severe degrees of glossitic atrophy—a circumstance which may explain the preservation of the gustatory sense in

many patients with pernicious anemia under such conditions. The tongue markings frequently begin their return toward normal long before the general and the hematopoietic responses to liver or its equivalent have been satisfactory, as related in Case II. The order of visible return of the papillae is the reversal of their order of disappearance. The fungiform papillae usually become distinctly prominent and then the filiform projections rapidly fill in the intervening spaces to render the fungiform papillae much less evident. The transformation of the smooth, glistening tongue of pernicious anemia to a normally surfaced member is a striking objective result of liver therapy (figure 4), but there is no apparent parallelism between the lingual and the hematopoietic responses to this form of treatment. The tongue may return to apparent normality as early as two weeks after the institution of adequate liver therapy.

Wider experience has refuted the assertion of Minot and Murphy⁵ rela-

FIG. 4. Illustrating return of filiform papillae in the atrophic tongue. The filiform papillae in the second print almost obscure the fungiform elements which are so prominent in the first print.

tive to the permanency of the glossitic remission. In an overwhelming majority this advantage is maintained, provided the dosage of the effective maturing factor is held at a sufficiently high level. Most of the recurrences of glossitic manifestations in the Wisconsin General Hospital have attended efforts to establish the maintenance dosage of liver or its equivalent by gradual withdrawal, or an intercurrent infection which has reduced the efficacy of a previously adequate dosage. Isaacs⁶ has made an especial study of the cyclic trend of relapses in pernicious anemia. In periods of seasonal depression glossitis of a mild order may, in his opinion, recur as a manifestation of such a relapse. As a rule, regardless of the background, the lingual changes may be controlled by increasing the amount of liver exhibited, although Isaacs, Sturgis and Smith⁷ feel that "the ingestion of liver does not seem to be entirely specific for this symptom."

Second in order of frequency as a cause of the atrophic tongue in temperate climates comes simple achlorhydric anemia of which Case III is a classical example.

Case III Mrs. A. E., a white housewife, aged 44 years, was admitted primarily for a chronic arthritic affection. The inventory by systems afforded some insight into vague digestive disturbances with intolerance for pork and onions. For nine months little meat had been eaten but the patient had partaken abundantly of fresh vegetables. Soreness of the tongue and mouth had been remarked for several months when "acid" foods were eaten. Citrus fruits would occasion serious distress, but lettuce and butter were craved. The menstrual cycles were regular. Of particular interest in the present relation were the physical observations of pallor and lingual atrophy. The tongue was raw in ap-

pearance and practically devoid of papillae. On admission the hemoglobin was 50 per cent and the erythrocytes 4.1 million. No free hydrochloric acid was demonstrable in the gastric contents even after histamine injection.

A conclusion of simple achlorhydric anemia was derived and the therapeutic trial of liver extract initiated. After two weeks of liver extract in adequate doses the hemoglobin was 45 per cent and the erythrocytes 4.2 million. Thereupon the treatment was shifted to Blaud's mass 4 grams daily and diluted hydrochloric acid 4 cc three times a day. The gain both from a clinical and from a laboratory standpoint was progressive from this time, so that two months later the hemoglobin registered 85 per cent and the erythrocytes 5.6 million. A month after the initiation of iron and hydrochloric acid therapy there was first noted a return of papillae to the anterior portion of the tongue. At this time the hemoglobin was 57 per cent and the erythrocytes 4.52 million. Clearly the lingual improvement anticipated any appreciable amelioration in the blood picture.

Simple achlorhydric or microcytic anemia has received wide attention in the recent medical literature at the hands of Kaznelson,⁸ Watkins,⁹ Witts,^{10, 11} and others. Witts¹⁰ reported glossitis in 25 per cent of 50 cases of simple achlorhydric anemia. The frequency with which frank changes to inspection were unattended by subjective complaint, led him to the conclusion of a much higher incidence. The clinical course of the glossitis to its ultimate atrophic stage can scarcely be distinguished from similar changes in pernicious anemia. In a series of cases under observation at the Wisconsin General Hospital the response to iron and diluted hydrochloric acid in full doses has followed the course of Case III. Occasional instances of simple achlorhydric anemia have been

encountered in which there has been no return of the lingual papillae in spite of a complete remission in the blood picture. The impression gathers that the lingual and the pharyngeal manifestations of this condition are much less amenable to treatment than the analogous states in pernicious anemia. Liver has not been effective in the treatment of simple achlorhydric anemia.

A somewhat less frequent situation attended by the atrophic tongue is represented in Case IV.

Case IV Mrs M P, a white housewife aged 41 years, complained of choking and difficult swallowing. A "nervous" constitution had given way to emotional outbursts over a period of four or five years. Vasomotor instability was evinced in hot flashes. For 1½ years inexplicable attacks of dyspnea had occurred paroxysmally without reference to effort. A sensation of tightness in the throat with occasional inability to swallow comfortably had recurred at intervals for ten years and more recently had lead to choking. Preceding the dysphagia for about ten years the patient had experienced repeated soreness of the tongue. In her judgment both of these conditions were becoming progressively worse. Pertinent to the present consideration were the marked pallor of the skin and mucous membranes, the atrophic tongue and the palpably enlarged spleen. From time to time during the hospital stay superficial apthae appeared in the mucous membranes of the nose and throat. The hemoglobin was 48 per cent and the erythrocytes 4.2 million on admission. The icterus index was 5 and the stools showed no ova nor parasites. There was no urobilinogen in the urine. The basal metabolic rate was determined as -3 and -2. Inability to pass the stomach tube precluded a determination of the acidity of the gastric contents.

This case fulfilled the diagnostic criteria of the Plummer-Vinson syndrome. Accordingly a close inquiry was made into her dietary and no essential principle was found lacking. Milk, cream and butter were taken

adequately, whereas eggs were not well tolerated. Fruits, except the citrus variety, and greens were enjoyed. Citrus fruits seemed to aggravate the soreness of the tongue and the dysphagia. Cereals, vegetables and puddings ranked as favorite foods. Meat was eaten sparingly, but the patient professed an appetite for the fat of meats as well as for butter. She volunteered the information that she had always been anemic and had taken "blood" medicine as long as she could remember.

After two weeks of Bland's mass 4 grams daily and diluted hydrochloric acid 6 cc three times a day, the hemoglobin rose to 70 per cent and the erythrocytes to 5.49 million. Coincident with the improvement in the blood picture the dysphagia became decidedly better and papillae returned to the tongue.

The so-called Plummer-Vinson syndrome was first described by Vinson¹² in 1922, since which time the literature has contained scattered references to the subject. (H S Plummer had applied the term hysterical dysphagia to this condition in 1914.) The majority of these contributions have merely added further examples of the condition or have sought to explain this obscure syndrome of glossitis, dysphagia and anemia, which usually responds miraculously to the passage of the esophageal sound. Moersch and Conner¹³ reported glossitic changes in 11 of 65 cases. The tongue is commonly quite painful and sensitive.¹⁴ Jones and Owen¹⁵ described the smooth, glazed tongue as devoid of all papillae or with irregular islands of persisting epithelium. Witts¹⁶ noted the close similarity of the glossitic changes in this condition to those of pernicious anemia, but expressed the opinion that apthae and circular areas of denudation were more common in the Plummer-Vinson syndrome. Witts likewise reported the tendency for the lingual

changes to undergo a complete remission *pari passu* with the general improvement. Occasionally a residual island of atrophy may persist. While achlorhydria is the rule, the administration of diluted hydrochloric acid apparently has no beneficial effect.¹⁶ Liver, also, is without specific action. The anemia responds most readily to transfusions, and iron is commonly effective as in Case IV.

The streptococcus was adjudged the responsible etiologic agent in the glossitis of pernicious anemia by Hunter,² Schneider and Carey¹⁷ isolated the streptococcus *viridans* in cultures from the deeper layers of the tongue and demonstrated this organism deep in the muscles of the tongues of pernicious anemia patients studied by biopsy. The scope of the present discussion does not admit of a consideration of the probable significance of this finding, but the overwhelming weight of evidence favors the contention that the streptococcal invasion of the tongue is incidental rather than causal in pernicious anemia. A rather striking example of streptococcal glossitis is cited in Case V, because of the etiologic problem it suggests.

Case V Miss J. J., a white nurse aged 40 years, complained of a sore mouth. For three years the gums and tongue have been almost continuously sore. Since the age of 16 years the patient has been periodically troubled with canker-sores on the gums, buccal mucous membranes and tongue. Lately the lips have become dry and sore. Occasionally a vaginal discomfort, likened to that of a canker sore, has been remarked by the patient. Unexplained subcutaneous hemorrhages have occurred in two fingers in the past nine months. For seven or eight years recurrent swelling of the right upper eyelid has developed at irregular intervals. Fatty foods were not well tolerated. Citrus fruits and tomatoes were avoided because

of the discomfort which they induced locally in the mouth. The mouth was the chief seat of pathologic findings to physical examination. The mucous membrane of the entire mouth and oropharynx was deeply injected and sensitive. The tongue was beefy with especial congestion at the tip and edges. Transverse furrows were apparent over its dorsum and the papillae were quite atrophic. Sublingual soreness and boggyness were observed. The gustatory sense for sour and bitter was lost, but sweet was promptly perceived. The hemoglobin was 75 per cent and erythrocytes 4.6 million. Free hydrochloric acid appeared in the gastric contents only after histamine. Repeated cultures of the tongue scrapings showed streptococci in overwhelming predominance. Sensitization tests for food, keratinoids and streptococci proved negative.

Nor do these examples exhaust the clinical conditions which are attended by the atrophic tongue. Probably the tongue of sprue most closely approximates that of pernicious anemia. Manson-Bahr and Willoughby¹⁸ gave a comprehensive consideration to this detail. The earliest manifestation in their experience was an increased sensitiveness to hot fluids, spices and tobacco smoke followed by a perversion to salt and to sweets. The fungi-form papillae were seen to stand out prominently toward the tip of the tongue as hyperemic dots. Aphthous ulceration of the buccal mucous membrane and tongue occurred on the rupture of tiny vesicles in their deeper layers. These aphthae induced marked tenderness and sensitiveness in the parts affected, especially the inner margin of the lower lip, the frenum, tip and sides of the tongue and less commonly the mucosa of the cheek opposite the lower molars. The chronic sprue tongue was smooth and polished. In their judgment while the oral symptoms may recur or persist

after the gastro-intestinal situation has been controlled, "it is a useful guide to consider a patient with obvious tenderness of the mucosa of the mouth and with unrestored function of the filiform and fungiform papillae as incompletely restored to health. The tongue and mouth should constitute an index of what is going on in the rest of the alimentary tract."

In pellagra, ulceration of the tongue is not uncommon along its edges. This ulceration may eventually lead to a complete denudation and the tongue assume a beefy redness. At this period mastication may be extremely painful and deglutition a torture. Again, widespread ulceration may be unattended by serious distress. The latter circumstance doubtless arises from the mental deterioration of the pellagrin in many instances. The deeper injection and the firm, sharp contour of the pellagrous tongue are in contrast to the moderately congested and flabby tongue of sprue. Denudation rather than atrophy accounts for the smooth tongue in pellagra. The response of the glossitic manifestations to proper dietetic management is one of the earliest measures of its success.

The anemias of pregnancy and the puerperium are frequently attended by soreness and atrophy of the tongue.¹⁹ As a matter of fact the early descriptions of pernicious anemia attended by atrophy of the tongue were in several instances^{20, 21} classical examples of the anemia of pregnancy. Keefer and Yang²² observed glossitis with atrophy in malnutrition attended by dysentery and anemia. Relief of the underlying condition resulted in a return of normal papillae. Lewis²³ noted glossitis with low papillae in a case of

pyloroplasty complicated by peritonitis and obstruction for which a jejunostomy had been performed. Meulengracht²⁴ reported atrophy of the lingual papillae with injection and blebs succeeding intestinal stricture, in a review of the blood changes attendant upon this condition. Isaacs, Sturgis and Smith⁴ noted the tongue in dibroriocephalus latus infestation to be smoother than normal but not atrophic. Glossitis with atrophy of the tongue has been observed in achlorhydria by Schneider and Carey²⁵ among others. Wilkinson and Oliver,²⁶ for example, found a sore tongue or an ulcerative stomatitis the outstanding feature in 25 of 53 cases with achlorhydria. Oatway and Middleton³ found a definite correlation between gastric anacidity and lingual atrophy. Witts¹¹ admitted the common coincidence of achlorhydria and glossitis, but pointed out the occurrence of the latter in certain cases of anemia and malnutrition in which the free hydrochloric acid of the gastric contents was normal.

From this review it may be concluded that glossitis with ultimate atrophy occurs in a considerable group of conditions. It is beside the purpose of this presentation to hypothesize as to the possible significance of this circumstance. Lewis²³ in a comprehensive survey of the subject, concluded that "there is no general agreement as to the cause of lingual atrophy in any of the conditions considered", although he clearly leaned toward a conditioned deficiency as the background. Castle and his fellow-workers²⁷ advanced further evidence in support of this position. Whatever the final answer to this question may be, the clinical significance of these lingual changes,

both in the diagnosis and the prognosis of the conditions discussed, must not be overlooked. To this end the ad-

vantage of serial tongue prints as a means of studying the progress of the glossitic process is strongly urged.

The Significance of Fever and Blood Protein Changes in Regard to Defense Against Infection

By

HOBART A. REIMANN, M.D., *Minneapolis, Minn.*

FEVER, one of the most constant and striking features characteristic of the invasion and growth of pathogenic microorganisms, has attracted the attention of physicians since the beginning of medicine. Hippocrates, Celsus, Sydenham and many others considered it of importance as a defensive mechanism against disease, "*vis medicatrix naturae*." This viewpoint prevailed generally until the nineteenth century when a number of observers took an opposite stand. Claude Bernard, Liebermeister and others devoted much attention to fever and believed it to be harmful. Their opinion in regard to the deleterious effect of fever on the body appeared to be greatly enhanced by the contemporary development of cellular pathology and the demonstration of "cloudy swelling" as a result of fever by Virchow. Their publications were widely accepted and led to the adoption of various measures for the purpose of reducing fever. Naunyn was one of the first to attack Liebermeister's teaching, and showed that fever

in itself was not responsible for the various pathological changes often found in febrile diseases, but that the damage was caused primarily by the invading organisms. It was admitted that extremely high or prolonged fever, as for instance in heat stroke, often produces pathological changes in tissues.

Recent clinical and experimental studies also show that excessively high body temperatures, induced artificially are harmful and may prove fatal.

Controversy in regard to the harmful or beneficial effects of fever reached its height late in the nineteenth century. The weight of evidence now appears to favor the latter contention. Experiments designed to show the beneficial influence of fever as a defense mechanism against bacterial infection may be divided into four classes,—the demonstration of (a) antibacterial and antitoxic effects of fever temperature *in vivo*, (b) the enhancement of antibacterial and antitoxic ability of the host by raising the body temperature, (c) the diminished resistance of the host to bacterial infection by lowering the body temperature, and (d) the beneficial effects of intercurrent infection and fever on other diseases.

Presented at the San Francisco Meeting of the American College of Physicians, April 5, 1932.

From the Department of Medicine, University Hospital, University of Minnesota.

As early as 1876 Heydenreich¹ noted that the spirilla of relapsing fever lost motility sooner at 40° C than at normal body temperature. Many other studies later showed that bacterial growth appears to be inhibited by temperatures over 40° C.^{2, 3} Yoshioka⁴ showed that pneumococci, when grown at 39° C, lost both virulence and specificity. Vibriolysin and tetanolysin were destroyed by heat *in vitro*, and guinea pigs heated by light treatment were more resistant to these toxins than unheated animals, according to experiments of Sonne.⁵

Filehne, Chienisse, Walter¹ and Trudeau showed that animals kept warm or heated were less susceptible to experimental infection than those whose temperature was lowered. Recently, Robertson,⁶ in observations on experimental pneumonia in dogs, noted that when morphine was given in quantities sufficient to produce a well marked depression of body temperature, subsequent infection with pneumococcus resulted in a severe, prolonged and widespread infection often accompanied by bacteremia and ending in death. The same quantities of pneumococci in unmorphinized dogs produced a mild localized disease lasting two or three days. Rolly and Meltzer,⁷ in 1908, showed that heated animals were more resistant to bacterial infection than unheated ones but were unable to demonstrate any special bactericidal substance in the blood, nor was there a constant degree of phagocytosis demonstrable in the heated animals. In other experiments they showed that phagocytosis became more active as the temperature exceeded 37° C until 40° was reached.

Temperature higher than 40° C interfered with phagocytosis.

Rolly and Meltzer,⁷ Ludke,² Friedberger and Bettac⁸ and others demonstrated an increase of agglutinins and hemolytic amboceptor by heating animals. The increase in titer of typhoid bacillus agglutinins as a result of fever due to other causes has been repeatedly observed both clinically and experimentally. The fact that chronic diseases are occasionally favorably influenced by intercurrent acute infection has been known for many years and has led to the common usage of hot baths and heliotherapy, which were already used by the ancients. In modern times, the inoculation of malaria or relapsing fever parasites, the injection of foreign protein or the use of diathermy are widely employed for the purpose of inducing therapeutic fever.

A new approach to studies on the effects of infection and fever has been furnished by observations in regard to the suspension stability of the blood. This phenomenon although widely observed for many years, then disregarded, was restudied and popularized by Fåhræus⁹ in 1921. Since then, hundreds of papers have appeared concerning studies of the suspension stability of the blood expressed as sedimentation time or speed of erythrocytes, in many diverse conditions.

Fever and a disturbance of the suspension stability of the blood may occur independently but usually occur together and accompany most if not all infectious diseases. The decrease of suspension stability was shown to be due to an increase of the globulin and fibrinogen content of the blood.

which occurs in most febrile infectious diseases and in certain afebrile conditions as in pregnancy and myeloma³⁸ Whether fever alone is responsible for the increase of blood protein or whether it is due to effects of the invading organism has not been decided Fåhræus believed it to be due chiefly to the effects of the virus Experiments by Frisch and Starlinger,¹¹ Puxeddo¹² and others, and studies in our own laboratory also indicate that fever alone, as induced by diathermy is not effective in causing marked increases in either globulin or fibrinogen³⁹ It is probable that a combination of factors in febrile infectious disease operates to produce plasma protein changes by stimulating globulin or fibrinogen producing organs, presumably the bone marrow or the endothelial system

With increase in the globulins, there occurs an increase in the viscosity of the plasma Then, as a result of an alteration of electrical charges¹⁰ the erythrocytes clump and settle rapidly In attempting to show the beneficial effects of a decrease in the suspension stability of the blood in regard to defense against infection, Fåhræus¹⁰ has shown that a slowing of the blood stream such as occurs in inflammatory tissue, permits the erythrocytes to form large clumps and as such they tend to occupy the axial current of the slowly moving stream according to physical principles As a result, leucocytes are crowded out and forced along the walls of the vessels to a favorable position for migration through the vessel wall into the area of inflammation (See Zinsser,¹³ p 300)

In returning to the subject of the aggregation of erythrocytes in plasma of increased viscosity, the question arises as to whether other suspended particles may not be similarly affected Leucocytes may be clumped¹⁴ but little attention has been given to the effects of plasma changes on bacteria^{15,16} Both erythrocytes and bacteria are known to carry negative electrical charges¹⁷ so that if erythrocytes tend to clump when the electrical equilibrium is disturbed by a change of plasma proteins, bacteria theoretically should be similarly affected If it can be shown that the changes in the plasma which accompany febrile infectious diseases favor the clumping of bacteria, another point will be added in favor of fever and plasma protein changes as mechanisms of defense against infection Bull,¹⁸ Rich,¹⁹ Cannon^{20, 21} and others have shown that the agglutination of bacteria is one of the most important steps in the recovery from experimental infection

EXPERIMENTAL

The following experiments were performed to determine the effect of changes of viscosity of the plasma and of other fluids on the clumping of bacteria

Several preliminary experiments were made to test the behavior of various kinds of bacteria when suspended in samples of plasma of varying viscosity Type II pneumococci, typhoid bacilli and Friedlander bacilli were suspended in plasma obtained from a normal individual and in plasma obtained from a patient suffering from lobar pneumonia due to type I

pneumococcus The viscosity of the normal plasma diluted 1 in 10 with 10 per cent solution of sodium citrate was 17 (Hess viscosimeter) and the suspension stability was such that the sedimentation time of erythrocytes, measured from the time the level of the red cell column dropped to the 60 mark on a tuberculin syringe, was over two hours The viscosity of the patient's plasma was 24 and the sedimentation time 10 minutes There was little or no perceptible effect on the bacteria when suspended in the plasma of higher viscosity than normal In some instances, there was a slight tendency to clump in the more viscid plasma

Very different results were obtained when minute amounts of specific immune serum were added to the plasma Tests were made by using immune serum obtained from a patient vaccinated with typhoid-paratyphoid A and B vaccine and paratyphoid B bacilli Instead of preparing dilutions of specific immune serum in normal physiologic salt solution as customary, dilutions were made in parallel in normal plasma and in plasma of increased viscosity When bacilli were suspended in the dilutions as arranged, clumping occurred in a far higher titer (1-10240) in the high viscosity plasma than in normal plasma (1-320)

Similar results were obtained when the viscosity of normal plasma was increased by the addition of gum acacia, as shown in table 1

The agglutination reaction shown in table 1 indicates that increase in viscosity enhances the specific agglutination effect of specific immune serum²² Results similar to these were obtained in experiments with type I pneumococci and type I antipneumococcus serum, and with type b Friedlander bacilli which agglutinate specifically in type II antipneumococcus serum

When smears stained with Wright stain were made from each tube and examined, microscopic clumping was found to occur within 10 minutes at 37° C Bacteria suspended in plasma of high viscosity or in plasma to which acacia had been added stained with difficulty They appeared pale and swollen or as if thickly coated with a gummy substance which prevented penetration of the dye Capsules of pneumococci and Friedlander bacilli were often accentuated In many preparations it appeared as if most of the organisms had vanished Resuspension or washing the organisms in physiological salt solution restored the normal staining reaction In most microscopic preparations made from suspensions of bacteria in colloidal solutions, bacteria appeared to be en-

TABLE 1

DILUTIONS OF SPECIFIC IMMUNE SERUM	40	80	160	320	640	1280	2560	5120	10240	20480	Control
Plasma + 2½% acacia	+++	+++	+++	+++	+++	++	—	—	—	—	—
Normal plasma	++	+	+	+	—	—	—	—	—	—	—

Microscopic agglutination of *Bacillus paratyphosus* B in specific immune serum diluted with high viscosity plasma (upper row) and with normal plasma (lower row) Reading made after 2 hours incubation at 37° C

meshed, even if not specifically clumped, in amorphous patches of lightly stained material presumably of the colloid itself. Bacteria suspended in plain broth or in salt solution were always diffusely scattered. Typhoid bacilli immediately became non-motile when suspended in 5 per cent solutions of gum acacia.

Increase in viscosity, as such, is apparently not alone responsible for the reactions described. Further experiments showed that solutions of other viscous substances—gum tragacanth, agar, egg white, starch paste, gelatin and glycerin adjusted to similar viscosity were less effective than gum acacia in enhancing specific agglutination.

Experiments with blood from a case of hyperinosis. Plasma obtained from a patient with myelomata contained 5.48 gm of fibrinogen and 2.27 gm euglobulin per 100 c.c.²³ The plasma viscosity was 7 as compared with 1.8, the viscosity of normal plasma, according to the technic used. The sedimentation

time was 5 minutes. Two dilutions, one of 1-100 and one of 1-200, of type I antipneumococcus serum were prepared with the whole blood of high viscosity and with normal blood as a control. Specific antipneumococcus serum seldom causes clumping in dilution as high as 1 to 200 when tested by the usual methods. Type I pneumococci were added to each tube. Stained preparations were made after 10 minutes incubation at 37° C.

Large clumps of pneumococci were found in preparations from the high viscosity blood in both dilutions of antipneumococcus serum. The leucocytes and platelets were not involved in the agglutination process and appeared to take no part in the reaction which is in harmony with the observations of Wright³ and others. Pneumococci were diffusely scattered in the smears made from both tubes containing normal blood and immune serum. An illustration of the type of clumping referred to is shown in figure 1.

FIG. 1. Type I pneumococci and type I antipneumococcus serum 1-200, incubated 10 minutes with (A) normal blood (B) high viscosity blood. Pneumococci are clumped in high viscosity blood with a minute amount of specific immune serum.

Similar results were obtained when the plasma of this patient and normal plasma were used with type II antipneumococcus serum and type b Friedlander bacilli. Clumping of bacilli occurred in dilutions of immune serum as high as 1-160 in the high viscosity plasma but only in the strongest concentration (1-10) in the normal plasma. An illustration of the clumping reaction is shown in figure 2.

were incubated for two hours. At this time stained preparations were made from the contents of each tube. The tubes were then kept in the icebox over night and read for macroscopic agglutination. The results of macroscopic agglutination are shown in table 2.

It is evident from the table that within a certain range, viscosity due to gum acacia has a striking effect on the

FIG 2 Type b Friedlander bacilli and type II antipneumococcus serum 1-40, incubated with, (A) normal plasma, (B) plasma of high viscosity. Bacilli are clumped in high viscosity plasma with a minute amount of specific immune serum.

Effect of varying grades of viscosity. Tests were made to determine the effect of varying degrees of viscosity with varying concentrations of specific immune serum. The experiment was arranged as shown in table 2. A solution of gum acacia was diluted in physiological saline solution so that varying degrees of viscosity were obtained. To the series of tubes containing these dilutions, type I antipneumococcus serum was added in the dilutions indicated. Heat-killed type I pneumococci were added and the tubes

sensitivity of specific agglutinins. Increase of viscosity beyond 5.6 tends to inhibit clumping. It is of interest to note that the range of viscosity at which clumping occurs best is close to the range of the viscosity of blood during certain infectious diseases.²³ The macroscopic results described checked with the microscopic examination of the clumping reaction made after two hours incubation. Identical results were obtained when type II antipneumococcus serum and type b Friedlander bacilli were used.

Effect of changes of viscosity in vivo Mice were inoculated intraperitoneally with 0.5 c.c. of an 18 hour broth culture of type I pneumococci and divided into three groups. One group was injected intraperitoneally with 0.1 c.c. of type I antipneumococcus serum diluted in 0.5 c.c. of normal physiological saline solution, the second group with 0.5 c.c. of a 10 per cent solution of gum acacia and the third group with 0.1 c.c. of serum diluted in 0.5 c.c. of 10 per cent acacia. The injections were arranged so that all mice received similar quantities of fluid intraperitoneally. Mice from each group were killed after 15, 30 and 60 minutes. Stained films were made from the peritoneal fluid of each mouse.

Results In mice receiving the minute amount of immune serum, pneumococci were found in great numbers diffusely scattered. The leucocytes were free and scattered. In mice injected with acacia alone, pneumococci stained poorly and many were scarcely visible, but no clumping was observed. Clumping of leucocytes was the most prominent feature. The most striking results were found in mice receiving both serum and acacia. Even at the end of 15 minutes most of the pneumococci had become invisible or had disappeared. A few tight clumps appeared here and there, either free, or attached to, or included in, agglomerations of leucocytes. Phagocytosis was slight. Leucocytes free in the peritoneal cavity appeared to take part in the clumping reaction, in contrast to their behavior in the blood. An illustration of the results obtained is shown in figure 3.

Discussion The non-specific effect of blood colloids on specific agglutination was observed by Bordet and Streng in 1909^{25, 26}. The agglutinative effect of the colloid was called conglutination and was recognized as distinct from the effects of specific agglutination. By adding ox serum Streng obtained a marked clumping of bacteria in dilutions of specific antisera which were too weak to cause agglutination unaided. He and Barikine²⁷ showed that conglutinin was removed by precipitating the globulin fraction of the serum. Dean²⁸ in 1911 reported similar observations and again showed that agglutinating serum contains two factors both of which are necessary to cause clumping, the one is a specific antibody, the other a non-specific substance which is possibly globulin. He also showed that a deficiency of the non-specific substance could be made up by the addition of globulin.

The experiments reported in this paper also show that at least two factors play a rôle in clumping of suspended organisms and that specific agglutination is influenced by various colloidal substances.

The mechanism involved in the agglutination or clumping of bacteria has received much attention. Gruber²⁹ in 1896 was the first to show that increased viscosity of bacteria caused them to adhere to one another and favored their subsequent englobement by phagocytes. The physicochemical principles involved in the clumping reaction have been studied by many observers. (See Northrop³⁰ and Zinner³¹ for references and discussion.) The outcome of much experimental

FIG. 3 Effect of viscosity on agglutination of type I pneumococci *in vivo* (A) serum from mouse injected intraperitoneally with type I antipneumococcus serum, (B) from a mouse injected with 10 per cent gum acacia solution, (C) from a mouse injected with both serum and acacia. In A and B the organisms are diffusely scattered. In B the leucocytes tend to clump and in C both pneumococci and leucocytes clump.

work indicates the complexity of the phenomenon. Bacteria in suspension appear to behave much like other protein particles. Their agglutination and precipitation depends largely upon repulsive and cohesive forces. Changes in the composition of the menstuum in which bacteria are suspended alter the cell surfaces, bring about changes in electrical charge and cause clumping.

The experiments reported in this paper concern the enhancement of specific agglutination brought about by changes in the plasma proteins as a result of febrile infections. The reaction was shown to be influenced by increase in the globulin-fibrinogen content of the blood which increased the viscosity of the plasma. The effects of increase of viscosity of the plasma could be reproduced by increasing the viscosity by adding other colloids, especially gum acacia, to the suspension. The effects were observed both *in vitro* and *in vivo*.

Increase of fibrinogen or globulin in the blood occurs in almost all infections, but whether fever in itself is directly responsible for plasma protein changes or whether these changes merely accompany fever and both are caused by substances liberated by the virus is as yet uncertain. It appears that plasma protein changes result from the stimulation or irritation of globulin- or fibrinogen-forming organs and commonly occur in afebrile conditions (pregnancy myeloma) as well. Studies by Lloyd and Paul³¹ indicate that fever alone does not produce plasma protein changes but that the effect is dependent upon the intensity of the infection. It has been shown also that elevation of the body temperature by

diathermy produced but slight and transient blood protein changes.³¹ On the other hand, marked changes are caused promptly within two or three hours by the parenteral injection of protein and non-protein substances.³² The indications are, therefore, that both fever and plasma protein changes may occur independently and are due to the effects of the virus. Studies of these factors are under way in our laboratory at present.

At any rate, I have attempted to show that the changes in the blood proteins and increase of blood viscosity which occur during infectious diseases may represent an important mechanism in the defense of the body against infection. A number of observers^{18, 19, 20} have shown that agglutination is an important factor in the defense mechanism of the host. Mudd^{33, 34} and his associates have shown that increase of cohesiveness closely parallels increase in phagocytosis. It has been shown in this study that the optimal degree of viscosity produced artificially *in vitro* closely approximates the degree of viscosity of plasma found to exist during infectious disease and that this viscosity favors agglutination of bacteria. Whether these changes are of teleological significance is difficult to say. The effects discussed are non-specific and mechanical in nature. The fact that increases of blood colloids appear to prepare bacteria for clumping and ultimate phagocytosis permits one to regard the phenomenon in the nature of an opsonin.

Certain instances at first appear to contradict the suggestion that increase of viscosity due to increase of blood globulin is an important factor in de-

fense against infection. It is known that diseases like kala-azar and leukemia, are peculiar in that they are accompanied by marked increase of the plasma proteins, yet they particularly predispose the patient to secondary infection. It has been shown,³⁵ however, that in the diseases mentioned there appears to be an inability to elaborate specific antibodies. The data presented in this paper indicate that increases in viscosity in the absence of specific immune bodies are without effect. A further and more contradictory example pertains to the fatal infection from avirulent R pneumococci in horses used for the production of antipneumococcus serum.³⁶ In this instance, horses whose blood is known to be exceptionally high in fibrinogen content had been highly immunized by the intravenous injection of living S pneumococci, yet in the presence of high specific immunity and high fibrinogen content of the plasma, they succumbed to infection.

Other evidence of the effect of increase of viscosity on specific agglutination has developed from an entirely different approach. Fitch, Donham, Bishop and Boyd³⁷ have shown that the presence of agar greatly enhances the specific agglutination of organisms of the Brucella group. They have applied the phenomenon to practical purposes in agglutination tests.

The demonstration of the increase of the effective range of agglutination by specific immune serum by increasing the viscosity of the menstruum raises a number of questions for future investigation. One pertains to the apparent non-specific reactivation of agglutinins during infectious disease, as for example, the reappearance

of typhoid agglutinins during other infections. During and after lobar pneumonia, to what extent does the increase of the agglutination titer of the patient's blood depend upon the strength of the specific immune bodies or merely upon the increase of the globulin or fibrinogen? A relationship between the suspension stability of the blood and the titer of specific typhoid agglutinins has already been noted by Vorschütz^{15b} and others. Finally what are the potentialities of increasing therapeutic effectiveness of specific immune serum by increasing the viscosity of the plasma by dietary or other measures?

SUMMARY

Evidence has been presented by many observers to show that fever exerts a beneficial influence in the defense mechanism against infection. It has been shown that temperature at fever levels tends to influence the growth of bacteria adversely, to diminish the potency of toxins, to favor phagocytosis and to stimulate the development of immune bodies.

In experiments reported in this paper it has been shown that the increased viscosity of the plasma which occurs during febrile infection as a result of increase of certain plasma proteins enhances the specific agglutination power of specific immune serum. Other investigators have shown that agglutination is an important factor in the restriction of bacterial growth and spread in the tissues. It is therefore suggested that the plasma protein changes which occur during infectious disease and enhance agglutination are important factors in the defense mechanism against infection.

Poisonous Spider Bites

Newer Developments in Our Knowledge of Arachnidism

By

EMIL BOGEN, M D, *Olwe View, Cal*

INCIDENCE OF ARACHNIDISM

ALTHOUGH poisoning resulting from the bite of a spider has been recognized from the earliest times, and instances were noted in this country more than two hundred years ago,¹⁸⁰ a review of the literature made in 1926 disclosed a remarkable amount of skepticism as to the real existence and seriousness of this condition. At that time more than one hundred and fifty cases of spider bite poisoning reported by more than thirty different observers in the United States were reviewed, fifteen cases studied at the Los Angeles General Hospital were presented, the clinical syndrome was described at length, the course and treatment outlined, and some experimental work on the effect of the venom on small animals was summarized.²²

In the five years that have elapsed since this work was published, arachnidism has become much better known in this country and cases are being recognized and reported with considerable frequency. Thus more than a dozen different authors have published accounts of over seventy-five addi-

tional cases of arachnidism in this country, and numerous reports have appeared in Australia, South America and elsewhere, on this subject. Personal communications have revealed more than a hundred other cases, hitherto unpublished, treated by a score of physicians in California, Florida, and other states.

In view of the fact that nineteen instances of this condition were seen at a single hospital in Los Angeles during the past year, it appears probable that the true incidence of the disease throughout the country annually exceeds hundreds, and possibly thousands, of cases. Several death certificates were made out from this cause in California during the past year and several others reported in the newspapers and in personal communications, so that even though the mortality rate is very low, the possibility of such fatal termination cannot be disregarded.^{11, 27, 120, 148}

By far the greatest number of poisonous spider bites in human beings have been attributed to the black widow, or shoebutton spider, the female *Latrodectus mactans*, and to related species in other countries. It is true that a few instances of poisoning due

to the bites of other kinds of spiders have been reported,¹⁴³ but in most instances these bites have resulted in local rather than in general symptoms,¹⁶⁰ and many cases have been so complicated by infection and other factors that a correct evaluation is impossible.²⁷ On the other hand, the female *Latrodectus mactans* has been observed in scores of instances, and its recognition established not only by the very vivid descriptions of the black spider and its red markings given by the patients, but on many occasions the actual specimen has been captured and submitted to competent authorities for identification.

Moreover, the astounding symptoms which develop after the bite of this spider are so striking and unique that there seems to be little danger of confusing it with any other form. Further experimental work with the spider and extracts of the poison glands in our laboratory have, for the most part, confirmed previous findings. The bite of the spider produced marked symptoms, sometimes fatal, in mice as well as in rats, in many but not all of the experiments so performed. As previously reported, however, no consistent effect was obtained by the injection of macerated extracts of the whole spider or of its glands alone into mice,

rats, guinea pigs, rabbits, cats or chickens^{22, 26}

The question arises whether there has been an actual increase in the number of cases of spider bite poisoning in this country, or whether the condition is simply being more often recognized. The numerous occasions

on which physicians, being told of the syndrome, recall similar cases which they had seen in the past and failed to diagnose correctly, suggest that the latter explanation is by no means unreasonable. On the other hand, numerous observers have noted an actual increase in the number of the spiders, and particularly a change in their habitat, so that now, instead of being confined mainly to little inhabited rural regions, they appear to have invaded the city homes and are frequently found within garages and bedrooms of populated houses.

Accounts are still being received of patients suffering from the bite of the black widow spider who were subjected to the additional trauma of a major surgical operation because of faulty diagnosis and confusion with acute surgical conditions.^{38, 69, 85, 129, 147} It is, therefore, again in order to call attention to the existence and semiology of this very interesting but not really rare condition.

Altogether sixty patients suffering from the bite of a poisonous spider have been treated at the Los Angeles General Hospital. The findings

of the earlier studies have been quite consistently confirmed, and additional information has been obtained in this larger group. Most of the patients were men, but seven, or twelve per cent, were females. The ages ranged from one to seventy-two years, but the majority were young adults. The

majority were native white Americans but seventeen Mexicans and five Orientals were included. Nearly half of the patients were common laborers, but six housewives, nine children, and more than a score of skilled workers, including a sheriff, a painter and a teacher were affected.

Most of the bites occurred in the more sparsely settled districts, the majority of them being entirely outside of the city limits of Los Angeles, but instances were noted in the more crowded neighborhoods also. The bites took place, for the most part, in

the evening or early morning in summer or autumn. The spider was seen and described in the majority of instances, but a number of cases were diagnosed from the characteristic clinical picture alone, often confirmed thereafter by a successful search of the premises for the spider.

The culprit was variously described as large, medium sized or small, but always as black, and smooth or shiny, and usually as being marked with red on the abdomen, especially on the ventral side, where the hourglass shape of the red mark was often noted. Many of the spiders, alive or dead, were brought in for recognition. They were located in an outdoor privy in half of the cases, but in this series there were ten patients who were bitten while in their own homes, most of them while in bed. Several cases occurred in automobiles or garages, and in several the spider was found in clothes which had been hanging in exposed places, on porches, garages, in yards, etc.

The site of the bite was on the penis or neighboring structures in half of the cases, but the extremities were bitten in sixteen instances, the body ten times and the head twice. This is a much higher incidence of extragenital localizations than has been previously reported, due to the fact that the spiders in the more recent cases has been found more often in situations other than the classical one beneath the seat of an outdoor privy.

The diagnosis was made with little difficulty in these cases, no other condition being even suggested in most of the more recent instances, even in the absence of a history of seeing the

spider, but in the earlier cases various abdominal conditions, ruptured gastric or duodenal ulcers, appendicitis with peritonitis, or renal or biliary colic were repeatedly suggested, as well as tabetic crises, food poisoning, pleurisy or pneumonia, and tetanus. Local infections with cellulitis or lymphangitis supervened in four instances.

DIFFERENTIAL DIAGNOSIS

The diagnosis of arachnidism due to the bite of the *Latrodectus mactans* spider depends upon

1 A history of exposure to, or actual experience of, the bite of the black spider. There is usually little or no visible lesion at the site of the bite.

2 Pain, starting usually in the region of the bite but not always, and spreading until most of the larger groups of muscles of the body are involved. Except in multiparous women, the pain is usually felt most intensely in the abdominal muscles. The pain increases, reaching its maximum about an hour after the bite, and is then evidently excruciating and agonizing, usually continuous but occasionally cramp-like or intermittent and manifested by writhing, doubling up and screaming or moaning.

3 Rigidity and muscle spasm, most notable in the muscles of the abdominal wall, which become board-like and hard, as in general peritonitis. It should be noted, however, that the rigidity is not confined to the abdomen, but that the intercostal muscles may contract, causing a "tightness" of the chest, and the back muscles may contract, causing a backache or stiffness of the back. The spasm of the calf muscles and other muscles of the ex-

trémities may be remarked, and the legs may be drawn up on the abdomen. True local tenderness, however, is usually entirely absent, or disproportionately slight compared to the intensity of the muscle spasm.

4 Increased blood pressure, usually 20 to 40 mm above the normal for that patient, hyperactive reflexes, especially the knee jerk, and an increase in the pressure of the spinal fluid are usually present.

5 A mild rise of body temperature, with occasionally, but not uniformly, a slow pulse, and a definite leucocytosis, with an increased percentage of polymorphonuclear leucocytes and a shift to the left in the Schilling count is to be expected.

6 Profuse perspiration, restlessness and anxiety, tossing about in agony and similar symptoms are usually seen. Nausea and vomiting, localized edema, twitching or spasms of the muscles of the extremities, and priapism and urinary retention are occasionally noted.

If these considerations are borne in mind, it is not usually difficult to distinguish a case of arachnidism from one of an acute surgical abdominal condition, renal or biliary colic, tabetic crises, food poisoning, pneumonia or pleurisy, tetanus, or any of the other conditions that may be suggested.

Poisonous spider bites could be, to a great extent, avoided if the general population were taught that these small and innocuous looking creatures are really dangerous and should not be tolerated in the vicinity of human beings. In order to avoid the unnecessary extermination of the many useful and desirable species of spiders,

the characteristics of this species should be made known and the peculiarities of its web popularized so that it may be readily recognized whenever encountered. This web consists of straggly, uneven, coarse viscous threads running in all directions in all three dimensions, with none of the geometrical exactitude which gives to the orbweavers or sheetweavers their esthetic charm. The poisonous female *Latrodectus mactans* may stretch its slim glossy black legs over as much as two inches spread. The under surface of the black globular abdomen usually bears a bright red patch shaped somewhat like an hour-glass. Once seen it is readily identified. Methods of extermination of the spider include destruction of its web and egg sacs, as well as the spiders themselves, with a broom, shoe, fly swatter or any other solid object available, or by the use of fly sprays or other special poison sprays, and by the encouragement of the natural enemies of the spider, both insects and birds.

Palliative treatment to alleviate the acute pains of spider bite poisoning is always sought, but usually is only partially effective. Opiates were given to most of our patients, but remark is repeatedly made of their relative inefficiency in this condition. Other sedatives and anodynes, including bromides, barbituric acid derivatives, and other coal tar compounds, were also used. The employment of hydrotherapy, in the form of hot baths, hot compresses and other applications, appeared to give considerable relief in many cases. Spinal puncture was performed only in a half-dozen cases, but the immediate relief following it in

most of these instances was so striking that it must be accorded special consideration as a therapeutic measure in this condition. The intravenous injection of a ten per cent solution of magnesium sulphate was given in one instance, with some apparent relief in symptoms.

Blood was taken from about one-third of these patients from one to ten weeks after the bite, and the serum was given to twenty-four patients soon after admission to the hospital. In three instances the treatment was repeated. The doses varied from two to thirty-five c c of this convalescent serum, given intramuscularly. It was administered from two to twenty-two hours after the bite was sustained, the average time being eight hours. The clinicians repeatedly reported that substantial relief from the symptoms followed soon after its administration.

The results of serum therapy in arachnidism are not readily evaluated, because of the variability of the symptoms and the fact that the milder cases might be expected to be more apt to escape this treatment. Analysis of the data available shows that the average

time of development of the symptoms was practically the same in those receiving the serum from those not so treated, and that the first signs of subsidence of the symptoms appeared after approximately the same interval of time. In the patients who received the serum treatment within eight hours of the bite, the main relief was obtained several hours earlier than in those not so treated, and complete cessation of symptoms and the recovery

from after-effects was somewhat more rapid in the treated group than in those receiving no such treatment.

Nevertheless, just as many clinicians feel that they can well dispense with the use of the antitoxic serum in the ordinary case of scarlet fever, potent and specific as this treatment is acknowledged to be, so it is thought that the convalescent serum in arachnidism, although theoretically correct and practically of apparent clinical value, is not an essential requisite in handling most cases of spider bite poisoning.

Perhaps it should be stated that despite its severe symptoms, spider bite poisoning is, in the majority of cases, a self-limited condition, and generally clears up spontaneously within a few days. Much suffering and even fatalities are due to injudicious treatment rather than to the venom itself. Thus, stimulants, caffeine, strychnine, adrenalin, and especially the lavish use of alcohol have no ra-

tional indication and are probably productive of more harm than good in this condition. Similarly, local treatment by incision, caustic chemicals, and even the actual cautery, is practically always too late to be of any value since the venom is so rapidly absorbed that systemic effects develop within a few minutes and generally reach their acme within an hour after the bite. On the other hand, such treatment is apt to open the way to local infection, since the spider usually lives in dirt and filth and the site of the wound is apt to be contaminated with germs. Since there is little or no local lesion, the simple application of any mild antiseptic, such as tincture of iodine, is preferable. The fact that four of our cases of spider bite poisoning thereafter developed local infections at the site of the bite, and others have reported deaths from similar infections, emphasizes the desirability of such local antiseptic application.

CONCLUSIONS

The black widow spider is found over more than half of the United States. Nearly four hundred instances of systemic poisoning from its bite have been reported. Unnecessary operations upon such patients could be avoided if all physicians recognized that an acute condition with rigidity of the abdomen, fever and leucocytosis, and occasionally nausea and

vomiting, may supervene as a result of the bite of a black spider. It may be differentiated, however, from acute abdominal lesions requiring surgical intervention by the presence of spasm in muscles other than those of the abdomen, by the absence of marked local abdominal tenderness, and by the concomitant rise in the pressure of the blood and spinal fluid. The mortality rate is low and patients usually recover spontaneously within a few days, but the suffering is intense and more than a dozen fatalities have been reported. Sixty patients have been treated at the Los Angeles General Hospital with no deaths.

The prevention of arachnidism depends upon popular education as to the danger of these spiders and the advisability of their eradication. Local treatment of the bites should consist of simple antiseptic applications, and additional trauma by incisions, cauterization, or the injection of hypothetical antidotes should be avoided. Stimulation and alcoholic drinks are usually contraindicated. Harmful surgery may be obviated by correct diagnosis. Opiates and hypnotic drugs may be used as palliative measures, together with sedative hydrotherapy and the reduction of intracranial pressure by the administration of hypertonic solutions or spinal puncture. Specific treatment with serum from convalescent victims is of value, particularly if administered early.

Studies on a Urinary Proteose

II. Skin Reactions and Therapeutic Applications in Hay Fever

By

WARD DARLEY, M D, and RICHARD W WHITEHEAD, M D,
Denver, Colorado

THE literature prior to 1919 dealing with the antigenic properties of protein cleavage products has been thoroughly reviewed by Fink¹ He briefly summarizes the numerous papers reviewed by stating that experiments with products of protein digestion show that proteins cannot be disintegrated much, if any, beyond the coagulable form without losing their sensitizing properties By experiments in which he prepared proteoses from egg albumin he demonstrated that proteoses have definite antigenic properties Auld,² in 1917, began to advocate the use of non-specific peptone therapy in the treatment of bronchial asthma and since that time he has published numerous papers on various phases of its use He uses the word "peptone" advisedly in that it represents a mixture of proteoses and peptones and he recommends Armour's peptone solution because of its high proteose content³ Many other investigators have used peptone solutions in one way or another for nonspecific desensitization in

the various allergic conditions^{4, 5, 6, 7, 8} Vallery-Radot and Giroud⁹ have used Witte's peptone solution intradermally in the treatment of hay fever

The presence of proteose in the urine excreted during suppurative and febrile conditions, malignancy, and tuberculosis has long been recognized¹⁰ The significance of this observation was not definitely understood although Wells mentions the possibility that the symptoms in these conditions may be due in part to proteose intoxication In 1928 Barber and Ornel¹¹ began to publish observations regarding the appearance of a proteose in the urine excreted during allergic conditions as well as in those just noted These investigators found the presence of the proteose to be the cause of a so-called "ether reaction" which was obtained as a result of extracting urine excreted during allergic symptoms with ether after previously acidulating with sulphuric acid A positive reaction consisted in the appearance of a waxy scum in the ethereal layer beneath the superficial froth In strongly positive tests the tube of urine could be inverted without spilling The more acute the allergic symptoms, the more positive the test They were able to ob-

From the Departments of Medicine and Physiology and Pharmacology, University of Colorado School of Medicine and Hospitals, Denver, Colorado

tain a precipitate from the ethereal layer by adding an excess of alcohol. Aqueous solutions of this precipitate gave the characteristic chemical tests for proteoses. The clinical significance of this urinary substance has been further investigated by Oriel^{12, 13, 14} and by Oriel and Barber¹⁵. After careful observation and well controlled experimentation they have demonstrated the following in the allergic patient. If the proteose is prepared from urine collected during a period when symptoms are present, his skin will usually respond with characteristic wheal formation after intradermal injection, reinjection will reproduce his allergic symptoms, and desensitization will usually result in an improvement or disappearance of his symptoms, if the proteose is prepared from urine collected when symptoms are not present, none of these phenomena will take place.

We have studied this proteose sensitivity in a variety of conditions^{16, 17} but this paper will deal exclusively with a series of hay fever patients treated during the spring and summer of 1931.

Proteose prepared according to the methods of Oriel and Barber¹⁵ was used as follows for skin testing. Tests were performed upon the volar surface of the forearm beginning with the control (1 cc N/10 sodium hydroxide in 9 cc of Coca's solution) just distal to the crease of the elbow. Below this the proteose dilutions were injected intradermally in the order of their strength at distances of 3 cm from each other. About 0.05 cc of solution was used for each injection. A positive skin reaction is character-

ized by the development of a wheal within from 5 to 10 minutes, from the edges of which one or more pseudopods develop (see figures 1 and 2). At the height of its development, which usually takes place in from 15 to 30 minutes, the wheal is circumscribed by a scarlet flare. The patient sometimes complains of itching. The wheal gradually subsides leaving an erythematous blotch which may not disappear for several hours. In a few instances, especially in the hay fever patients, this area of erythema has gradually increased in size up to 12 hours and has been accompanied by tenderness and a sense of heat. In very sensitive patients, especially those subject to asthma, we have found that a focal reaction may follow either the intradermal test or the subcutaneous injection of too large a dose. Consequently it should be stated that for the past few months we have been resorting to the scratch method of testing for sensitivity in order to avoid untoward reactions. For this purpose we apply a few drops of the N/10 sodium hydroxide-proteose solution to a scratch upon the volar surface of the forearm using N/10 sodium hydroxide as a control.

The initial dosage for desensitization is best arrived at by selecting the dilution next below that which gives the least positive intradermal reaction. The first dose is usually 0.05 cc subcutaneously. Injections are given at from three to four day intervals and the dose is gradually increased or decreased as indicated by the patient's clinical progress. In our experience no focal reactions have developed if desensitization were started with the

weak dilution as indicated. If a focal reaction does occur, the next weaker dilution should be used.

The group of hay fever cases herein presented represents one of the numerous allergic conditions in which we have studied the proteose reactivity. In all we have investigated the proteose sensitivity in over 100 patients including, aside from hay fever, such conditions as asthma, serum sickness, eczema, erythema multiforme, migraine and rheumatoid arthritis. Of these we have found hay fever and eczema the most prompt to yield to proteose desensitization. We feel that the presentation of this series of hay fever cases should be of interest because of the very suggestive results obtained and also because of its possible bearing on the study and therapeutics of allergic diseases.

Case I Male, age 17. Onset of hay fever in early summer. Sensitive to orchard grass, timothy, June grass, lambs' quarter, Kochia, pigweed, pasture sage, and false ragweed. This patient was studied merely as a matter of interest to see if proteose prepared from a case of hay fever would induce a positive intradermal reaction. The test proved to be a plus 2*. Treatment with the proteose was not attempted.

Case II Male, age 21. Onset in early summer. Sensitive to various grasses and giant ragweed. Given pollen injections for hay fever during the previous season with no results. Intradermal proteose test, plus 2. Given proteose injections at biweekly intervals with immediate and complete relief of symptoms. After three weeks the patient moved to Michigan, proteose injections were stopped, and the hay fever returned.

Case III Female, age 29. Onset in early summer. Sensitive to June grass, timothy,

*plus 2=moderate reaction, plus 3=marked reaction, plus 4=very marked reaction

orchard grass, lambs' quarter and Kochia. Intradermal proteose test, plus 2. Previous pollen desensitization with only fair results. After two injections the symptoms entirely cleared and the patient did not return for further treatment.

Case IV Female, age 30. Onset in early summer. Sensitive to pasture sage, orchard grass, Russian thistle, broad and narrow leaf cottonwood, pigweed and Indian hair tonic. Treated during previous seasons with pollen injections with slight relief and was taking pollen at the time proteose was prepared. Intradermal proteose reaction, plus 3. Proteose administration was started in conjunction with the pollen desensitization with the result that added relief was obtained although hay fever still persisted to a mild degree.

Case V Female, age 29. Onset in early summer. Sensitive to pigweed, Kochia, Russian thistle and lambs' quarter. Pollen injections during the past season with good results. Had frequent attacks of urticaria which became aggravated during hay fever season. A proteose was prepared in March for the urticaria to which she was skin sensitive and from the administration of which she derived some benefit. With the onset of hay fever another proteose was prepared to which she gave a marked intradermal reaction. After the administration of the proteose the hay fever would improve but as the dosage was increased the urticaria would become more pronounced. Consequently the treatment of this particular case was not entirely satisfactory.

Case VI Female, age 8. Onset in early summer. Complicated by asthma during the previous season. Skin tests for pollen sensitivity not done. The intradermal proteose test was violent in that erythema persisted for over 12 hours. Following proteose administration the symptoms cleared completely and there was no recurrence of her asthma.

Case VII Female, age 39. Onset in early summer. Complicated by asthma during previous season. Sensitive to pasture sage, pasture sage, pigweed, Russian thistle and Indian hair tonic. Received pollen injections the year before with only slight relief of hay fever, asthma recurred.

usual Intradermal proteose reaction was plus 4, and was followed after two hours by an aggravation of the symptoms. Proteose desensitization resulted in considerable relief and the asthma was practically absent as compared with the previous year. In August the hay fever became somewhat worse. Although it was possible that certain of the weeds were responsible for this aggravation another proteose was not prepared.

Case VIII Female, age 39. Onset in early summer. Possible pollens concerned in the etiology not determined. Intradermal reaction to proteose was plus 3, and following the test there was an increase in the nasal discharge. Desensitization with the proteose resulted in a great improvement, the patient suffering only an occasional attack.

Case IX Female, age 17. Onset in early summer. Complicated by chronic sinusitis. Sensitive to many of the grasses and to Russian thistle. Desensitization with pollens gave no relief in 1928, 1929 or 1930. Intradermal reaction to proteose, plus 3. Relief from desensitization was complete for one month and a half (the middle of August) when mild symptoms returned. A second proteose solution was not prepared.

Case X Male, age 45. Onset in early summer. Sensitization tests for the pollens not done. Intradermal reaction to proteose, plus 3. Relief from desensitization was considerable though not complete.

Case XI Female, age 35. Onset in early summer. Complicated by acne. Pollen sensitization tests had been performed before but results were not known to the patient. Previous desensitization gave no relief. Intradermal proteose reaction was plus 4, the erythema increasing up to 12 hours. Relief after desensitization was complete and it was also of interest to note that the acne cleared completely and there was improvement in the general condition.

Case XII Female, age 33. Onset in late summer. Pollen desensitization every year since 1925 gave good results. Intradermal proteose reaction, plus 3. Complete relief obtained after proteose desensitization.

Case XIII Male, age 52. Onset of symptom in late summer. No information

as to pollen tests or previous treatment. Intradermal proteose reaction was plus 4. Marked relief obtained following proteose desensitization.

The most important features concerning this series of cases are summarized in the accompanying table.

It has been recognized that only certain organs of the body may exhibit allergic manifestations. Bronchial musculature or nasal mucous membrane may be sensitive to a given antigen while the skin may or may not show an allergic response.

Alexander¹⁸ reviews this matter quite completely and points out that while the skin test is not always of much help in such conditions as asthma, urticaria and eczema, it is quite reliable in hay fever (between 90 and 95 per cent of the cases). None of our hay fever cases gave a negative or questionable dermal reaction. The standards for the interpretation of the intradermal test must, of course, be arbitrary. We interpret the responses as slight, moderate, marked and very marked, or plus, plus 2, plus 3, and plus 4, respectively. Reference to figures 1 and 2 will afford an idea as to our standards for judging the degree of reaction. Figure 1 exemplifies a marked (plus 3) and figure 2 a very marked reaction (plus 4). Focal reactions consisting in an aggravation of symptoms occurred in cases V, VII, VIII, and XII subsequent to the intradermal test. While no asthmatic attacks were induced the possibility of their occurrence must not be overlooked, and since constitutional reactions may assume serious proportions it should be stated again that we have decided to abandon the intra-

SUMMARY OF RESULTS
OBTAINED BY PROTEOSE DESSENSITIZATION IN HAY FEVER

CASE NO	INTRA- DERMAL REACTION	FOCAL REACTION	ONSET OF HAY FEVER	TIME UN- DER OUR OBSERVATION	INTERVAL FOR THERAPEUTIC RESPONSES	DEGREE OF RELIEF OBTAINED	MISCELLANEOUS
I	2 plus	0	Early				
II	2 plus	0	Early	3 weeks	24 hours	Complete	To Michigan where symp- toms returned
III	2 plus	0	Early	3 months	24 hours	Complete	Received only 2 proteose Injections
IV	3 plus	0	Early	2 months	2 weeks	Partial	Pollens given simultaneously Proteose gave added relief
V	3 plus	+	Early	4 months	1 week	Partial	Complicated by urticaria One improved at ex- pense of other
VI	4 plus	0	Early	4 months	1 week	Complete	Asthma previous summer No asthma after prote- ose desensitization
VII	4 plus	+	Early	2 months	1 week	Partial	Very little asthma as com- pared to the year before
VIII	3 plus	+	Early	1 month	1 week	Partial	
IX	3 plus	0	Early	3 months	1 week	Complete until August	Symptoms returned in mid-August
X	3 plus	0	Early	2 months	1 week	Almost Complete	
XI	1 plus	0	Early	3 months	24 hours	Complete	Acne cleared Improve- ment in general condi- tion

dermal test in favor of the scratch method

Eleven of the thirteen cases were of the early type of hay fever, two of the late. Where pollen desensitization is attempted the best results are obtained with the early type. Our results do not prohibit the assumption that proteose desensitization would be any less effective in the late than in the early types. The results obtained from pollen desensitization vary somewhat and depend to a certain degree upon the experience and skill of the physician administering the treatment. Thommen,¹⁹ after reviewing the reports of various investigators, gives average results obtained as follows: complete relief 10 to 30 per cent, almost complete relief 24 to 40 per cent, partial relief 20 to 30 per cent, and no relief 9 to 12 per cent. The results obtained from proteose desensitization compare very favorably with those ordinarily obtained following pollen administration. In comparing the results obtained from the two types of therapy it must be remembered that in order to obtain the most satisfactory response to pollen desensitization the patient must be under treatment for from two to three months before the onset of the hay fever is expected. Pollen treatment instituted after the onset of symptoms is frequently unsatisfactory. On the other hand proteose therapy is of value only after symptoms appear. In view of this consideration we feel that the use of the patient's proteose should be a distinct and valuable aid in the management of hay fever.

Furthermore, it is very likely that the use of proteose in the late type of

hay fever would make it possible for a greater number of patients to obtain relief. Case IV suggests another possible use for proteose. This patient received the preseasonal pollen injections for several weeks. When the trees and grasses began to pollinate her symptoms of hay fever appeared. At that time proteose therapy was instituted as a complementary measure. Under this regime, although the symptoms did not entirely clear, she felt that she had obtained definite additional relief. The reason for this added relief may be that the patient was sensitive to pollens which were not included in treatment initiated earlier in the spring. Cases VII and IX obtained great relief early in the summer, but with the pollination of the weeds later in the season the hay fever returned. The observations made in these cases strongly suggest a specific relationship between the various pollens and their corresponding proteoses. Cases V and XI presented certain other very interesting points relative to the specificity of the urinary proteose. Case V was complicated by urticaria which had been present for some time prior to the onset of hay fever. It is probable that proteose prepared after the onset of hay fever had antigenic substances present which were also associated with the urticaria. Since a dosage that seemed to cause improvement in the hay fever appeared to aggravate the urticaria, it is assumed that the respective antigenic substances were specifically related to the two conditions and that they were present in conflicting concentrations which precluded the attainment of satisfactory

results. On the other hand Case XI demonstrated quite the opposite in so far as results were concerned. The patient had had acne for years. Desensitization resulted in complete relief of both and to date (March, 1932) the acne has not returned. It is also of interest to note that her general condition has greatly improved. Here again it is to be assumed that antigens were obtained in the proteose which were concerned in the production of acne as well as hay fever.

Conclusions such as these strongly support the contention that desensitization with the allergic patient's own proteose is based upon the principles of specific therapy.

The use of nonspecific protein desensitization in an effort to counteract reactivity to specific proteins has undoubtedly played a most important rôle in the treatment of allergic disease. Auld²⁰ has recently advocated the use of a special "serum peptone" which is partially prepared from the patient's own blood. If a normal individual eats eggs 48 hours after being injected intracutaneously with serum from an egg sensitive patient, a wheal will develop at the site of the injection. This is a variation of the Prausnitz-Kustner reaction and demonstrates the fact that specific antigenic substances are circulating in the blood stream. If this is true they must be present to a certain extent in the peptone which Auld describes. From the same standpoint the use of auto-hemo-therapy as advocated by Kahn and Emsheimer,²¹ Henske²² and Ghosal²³ is also in part specific in its principle. Flandin²⁴ strongly advocates intradermal injections of the patient's own serum in the

treatment of hay fever. If the antigens concerned in the production of allergic symptoms are circulating in the blood they should no doubt be eliminated through the kidneys as well as through other channels. Duncan^{25, 26} in 1912 and 1914 advocated the oral administration of the patient's own urine in certain diseases, basing his treatment upon the belief that certain bacterial and tissue toxic substances were eliminated through the kidneys and that ingestion of these would stimulate specific antibody formation. Two cases in which the patients claim to have been relieved from asthmatic paroxysms by drinking their own urine have come to our attention. While desensitization by the oral route is of doubtful value it is of interest to note that Thommen²⁷ believes he has induced relief in a case of hay fever following the oral administration of ragweed pollen in large doses.

The work of Oriel and Barber¹⁵ demonstrates quite conclusively that the antigenic substances which they have recovered from the urine of allergic patients are specifically related to the antigens primarily responsible for the symptoms. Proteose obtained from a case of serum sickness will stimulate wheal formation when injected intradermally in other individuals known to be sensitive to horse serum. They showed further that the proteose from a case of serum sickness would induce asthma when administered subcutaneously in rather large dosage to a "horse-asthmatic." By the use of the Prausnitz-Kustner reaction Barber and Oriel advance further evidence as to the specific nature of the urinary proteose. Serum

from an individual suffering from serum sickness was injected intradermally at two points in a normal individual. Twenty-four hours later proteose prepared from this case of serum sickness was injected intradermally in one of these areas and proteose prepared from a non-serum sensitive individual was similarly injected in the other. A positive reaction as evidenced by wheal formation appeared in the area injected with serum proteose, no reaction occurring in the second or control area. Oriel¹⁴ using the uterus of a guinea pig which he had sensitized with proteose prepared from a milk sensitive patient observed a strong contraction when milk was added to the perfusing fluid in which the uterus was suspended. Similar results were obtained with a uterus sensitized to milk when the proteose was added to the perfusate.

Many of our observations substantiate these findings. One of our patients presented a violent generalized urticaria following the ingestion of a breakfast food containing flax to which she was found to be sensitive. Proteose was prepared from this patient and tested in another patient known to be flax sensitive. A marked local reaction was obtained. Similar reactions were observed when proteose prepared from a case of serum sickness was tested intradermally in serum sensitive individuals. Two hay fever patients each sensitive to the same pollen will respond with positive intradermal tests to each other's proteose.

The significance and exact origin of this urinary antigenic substance is somewhat problematical. Early workers in the field of immunology recog-

nized the possibility that the symptoms of anaphylaxis might be due to products of parenteral digestion or to products formed as a result of the reaction between the primary antigen and the sensitized tissue. Oriel and Barber¹⁵ after reviewing the experimental work of Lewis, Dale and Manwaring, consider that the urinary proteoses which they have found in all probability consist of these "secondary antigens" which are formed as a result of the interaction between the "primary antigens" and the sensitized tissues of the body.

Regardless of the origin of this antigenic substance found in the urine of allergic patients it is evident from the results reported by the original investigators and also from the hay fever cases reported in this paper that desensitization with homologous urinary proteose is of great practical importance. Many cases of allergy are seen in which the primary antigen is obscure and if a patient can be desensitized with his own proteose much is to be gained. Other cases occur in which it is probable that the primary antigen is derived from metabolic processes, or as the result of low grade infections, and in such cases it is difficult to desensitize a patient by the usual methods.

It must be understood that further investigation and experience with this urinary substance is necessary in order to arrive at a better understanding regarding its origin, significance and technique of application. We feel that the work of Oriel and Barber is of great importance in that it may open the way toward the solution of many problems of an allergic nature.

CONCLUSIONS

The literature regarding the antigenic properties and uses of proteoses is briefly reviewed laying particular stress upon the work of Oriel and Barber

Urinary proteose was prepared according to the original methods of these investigators and the intradermal and therapeutic response determined in twelve cases of seasonal hay fever. All cases gave positive intradermal reactions to their respective proteoses and improved after desensitization.

These cases are discussed at length regarding the clinical results obtained and also regarding the contention that

a given proteose is specifically related to a given antigen. The work of Oriel and Barber is briefly discussed relative to this point and confirmatory observations by us are indicated.

The probable origin and significance of this urinary substance is also mentioned in an effort to point out the important rôle which it may play in the future study and treatment of allergic diseases.

The authors wish to express their appreciation to Dr V B Fischer and Dr P A Dickman for data on Cases X and XI and Cases VIII and IX, respectively, and to Dr C N Meader for assistance in revising the manuscript.

The Successful Treatment of Hay Fever and Pollen Asthma

By ALEXANDER STERLING, M D, Philadelphia, Pa

DESENSITIZATION with pollen extracts for hay fever patients has been in vogue for the last fifteen years. The method originally conceived by Walker, Cooke, and others has not changed a great deal over that period and even now the treatment by the general practitioner of patients with hay fever and hay fever and asthma consists of a series of fifteen injections at weekly intervals. There has been so much controversy regarding beginning and protective doses, types of doses, etc., that there scarcely seems a way for the general practitioner to determine preference for any of the so-called "treatment sets" now on the market. Of these various "sets", there are many which are similar in contents and which are alike in that they are successful in only twenty per cent of all hay fever patients. Physicians and patients alike have informed me that pollen desensitization is of no avail, because they have tried this, that, and the other manufactured product with no success. The complainings have reached the stage where the practitioner says that there is no relief for hay fever, and at times insists that these "treatment sets" cause an even worse condition in the patient.

It is unfortunate that from the very

beginning of pollen therapy there was no standard for the preparation of pollen extracts nor any standard treatment adopted by allergic societies and recommended to pharmaceutical houses. The conditions existing, which I would like to explain and attempt to solve, are several.

First, there is no standardization in product of the various numerous pollen extracts now available. The pollen extracts are obtained from menstrums of saline, alcoholic saline, glycerol saline, and other types. All sorts of percentage compositions are resorted to in the make-up of the menstrums. I have experimented with various types and have found that if the pollen is extracted from a menstrum of fifty per cent glycerin and fifty per cent buffered salt solution, nearly perfect results are obtainable. All menstrums which do not contain glycerin are unstable. They are potent only when freshly prepared, when constantly kept on ice, or when received from the manufacturers. They quickly lose potency with changes in temperature or after certain intervals of time. These results are not dependent entirely upon the extraction liquid. Another fault existing in the makeup of the various pollen extract is in the standard of measurement. The various units used

to grade the strengths of pollen extracts range from protein nitrogen units (each unit equivalent to 0.001 mg of protein nitrogen) to pollen grain units (the amount of pollen grain extract from 0.001 mg of pollen)

Second and most important, no preparation on the market has sufficient material made up in a proper way for correct desensitization and successful results. It would be rather illuminating at this time to examine several of the products now in common usage.

Product number 1 contains three 4 c.c. vials of extracts of various pollens of particular groups. The three vials contain various proportions of pollen grains per cubic centimeter and furnish sufficient material for the usual fifteen dose treatment. The course of injection treatment is so constituted that the dosage begins with two pollen units, and the protective dose furnished is 1200 pollen grain units. A higher concentration is available in a 4 c.c. vial containing 2000 pollen grain units per cubic centimeter.

Product number 2 is a mixture of various pollen extracts standardized to contain about 2000 pollen grain units, or 500 protein nitrogen units per c.c. The extract is supplied in 5 c.c. vials and it is suggested that the practitioner adopt a graduated dosage beginning with 1/20 c.c., and progressing in either twentieths or tenths of a c.c. so as to obtain thirteen injections from the 5 c.c. vial. A fifteen dose treatment package of graded doses proceeding from 100 pollen grain units to the protective dose of 4000 pollen grain units is also manufactured. Each dose is in a separate syringe.

Product number 3 is standardized

according to the "protein nitrogen unit." This product is in two 5 c.c. vials; the starting dose is 5 units and the highest dose is 100 units. Sixteen doses are offered for injections and if larger doses are required another vial is offered, the highest dose being 250 protein nitrogen units.

Product number 4 contains four 3 c.c. vials and one 1 c.c. vial. It is an alcoholic saline pollen extract ranging in dilutions (volumetric method) from 1/10,000 to 1/100. The highest dose suggested is 5 minims of 1/100 dilution. Similar products are manufactured by other well known firms. They are all proponents of "treatment sets."

The doses, as can be seen from the above, range from between 2 pollen grain units and 100 pollen grain units as the lower level, to the apparently highest protective doses of from 1000 to 4000 pollen grain units. In a single exceptional case only does the highest protective dose reach anywhere near the correct figure of 10,000 pollen grain units. The highest dose suggested by the pharmaceutical houses is between 3 and 5 minims of a one per cent solution (or 0.025 or 0.030 nitrogen units), which they consider sufficiently protective.

For several years I have had five groups of 10 patients, each of whom I have treated with various advertised treatment sets. Only twenty per cent of these patients were benefited. Furthermore, only those who had hay fever were benefited. Those who had hay fever and asthma were not relieved by these preparations. Not until I began to use a three per cent concentrated pollen extract in various dilutions did I achieve nearly perfect re-

sults in 90 to 95 per cent of patients

Standardization of pollen extract, as mentioned above, by the protein nitrogen unit does not hold good for the reason that it has been proved by investigators that the carbohydrate fraction of pollen is just as responsible in the production of hay fever and asthma symptoms as the nitrogen fraction. I therefore have selected the pollen grain unit which is the quantity of pollen weight per unit of diluent. For example, 3 gms of pure washed pollen to 100 c c of glycerol and buffered salt solution is passed through a Berkefeld filter after one or two days standing. This extract contains approximately 30,000 to 32,000 pollen grain units per 1 c c which is a three per cent concentrated pollen extract. The reason why I limit myself to a three per cent pollen extract is that it has been demonstrated by many investigators that a three per cent concentrated pollen extract is equivalent to a saturated solution of pollen.

I use the following *dilutions*

Dilution No 1 Five minims of 3 per cent concentrated pollen glycerol extract to 10 c c diluent. Each minim containing 57 pollen grain units (The diluent that I favor is a sterile physiological salt solution containing 0.2 or 0.3 per cent carbolic acid). I find from my experience that any solution which contains from 30 to 50 per cent glycerol is very painful when injected.

Dilution No 2 Ten minims of 3 per cent concentrated pollen glycerol extract to 10 c c diluent. Each minim containing 114 pollen grain units.

Dilution No 3. Twenty minims of a 3 per cent concentrated pollen glycerol extract to 10 c c diluent. Each

minim containing 228 pollen grain units.

Dilution No 4. Forty minims of 3 per cent concentrated pollen glycerol extract to 10 c c diluent. Each minim containing 456 pollen grain units.

Dilution No 5 Eighty minims (5 c c) of 3 per cent concentrated pollen glycerol extract to 10 c c diluent. Each minim containing 912 pollen grain units.

Treatment. The most important factor in this work is to begin treatment with a dose small enough to give a local reaction not exceeding one inch (from 2 to 2.5 cms) in diameter. Quite often I find that the 2 minim dose of dilution 1 gives quite a large local reaction, sometimes accompanied by a constitutional reaction. In those cases I am compelled to make another dilution (1 A) containing about 2.5 minims of 3 per cent concentrated pollen glycerol extract to 10 c c diluent. This dilution contains about 28 pollen grain units. The first injection may even go down as low as 14 pollen grain units, in order to obtain a local reaction not exceeding one inch in diameter. It is here, in the beginning of treatment, that the only difference between a strongly sensitive and a weakly sensitive patient's dosage occurs. There is no necessity for complicating the treatment with various classifications of sensitivity A, B, C, and D as it is being practiced in some clinics. The protection doses in all cases are approximately the same.

Having obtained the starting dose (that which produces a local reaction not exceeding one inch in diameter) whether it be in solution 1, 1A, or 1B, the next dosage is four minims of that

solution The dosage of dilutions 1, 2, 3, and 4, is gradually increased consecutively to 4, 6, 8, 10 and 12 minims When changing from one solution to the next the first dose of the next vial may be 4, 5, or 6 minims The reason why I start with four minims of the following dilutions (which is a repetition of the dose) is to prevent a reaction from too large a dose from the next vial in case of difference or freshness of the pollen extract When the dose reaches solution 5, (which is approximately 1 per cent concentrated pollen extract), injections increase 1 minim daily until 12 to 15 minims are reached before the pollination periods of the respective seasons That, in the majority of cases, furnishes the highest protective dose

A suggestion of all pharmaceutical houses is that injections should cease with the beginning of the season. That is faulty The patient should receive injections of the highest protective dose (from 12 to 15 minims of 1 per cent pollen extract) throughout the season at least once a week In severe seasons, at the slightest appearance of mild symptoms my patients receive injections every day for a few days until 18 to 20 minims of solution 5 are given That, in some cases is the highest protective dose In the severest cases I find that the protective dose is about 15,000 pollen grain units In this way through these various procedures I have been able to attain perfect results in 90 to 95 per cent of patients no matter how severe the previous pollen intoxications

Discussion The shortcomings of the 15 dose treatment sets on the market are as follows

a The protection dose is in none of the sets sufficiently high for a complete relief

b The series of injections should not stop at the dose which gives the reaction but should either repeat or go back to a weaker injection In case of a constitutional reaction somewhere along the line the dose cannot be reduced or repeated on account of lack of material in the "treatment sets"

c Instructions to the general practitioner by most pharmaceutical houses state that the last dose (15th) should be given at or about the beginning of the respective pollination periods This conveys the impression to the physician and in turn to the patient that they are going to stay well and protected for the 6 to 8 weeks of the season, which is absolutely not justifiable Only one out of 15 or 20 may remain protected All others must have the maximum dose repeated every week for the season if protection is to be maintained

d The advice given by various clinics and certain manufacturers to increase the dose in the course of desensitization by 100 per cent or 50 per cent, is entirely wrong A patient can never be favorably desensitized to a higher strength by consistent doubling of the strength of the injection

In regard to reactions there are several considerations The patient must be kept in the office for at least one-half hour following the injection so that in case of any reaction from 3 to 5 minims of adrenalin may be administered

After a reaction the following day's injection should be 2 minims below the dose which provoked the reac-

vious reaction The dosage should gradually be worked up by 1 minim increases and after the previous reaction stage has been passed, increase may again be made by 2 minims

Patients receiving dilution 5 should never be increased by more than 1 minim at a time I have seen patients give violent reactions to, let us say, 7 minims of dilution 5 The following day they were given 5 minims of dilution 5, followed by a 1 minim increase every day, until receiving 10, 12, and even 15 minims without the slightest reaction The presence of a reaction does not mean that the patient is protected On the other hand, it merely reveals that the patient is not yet prepared for that particular dose and he must be worked up to it again by daily injections

Occasionally one finds patients whom you cannot work up to the protection dose Such patients occur in a proportion of 1 in about 15 or 20 In these cases increase of dose is halted and the highest dose the patient can receive without untoward reaction, is injected In this type of patient we achieve 80 per cent favorable results, and even though the protective dose has not been reached, the symptoms, if any, will be mild. It has been my experience that such patients do reach their protective dose during the second year of treatment

It is important to note that

1. There are from 20 to 25 injections given before there is any possibility of reaching dilution 5

- 2 The time interval is daily or even twice daily in the milder dilutions All injections are to be given intradermally, if possible

- 3 There are about 15 to 20 injections of dilution 5 necessary as a protective dose to be reached before the beginning of pollination of the summer (grass) and fall (weeds, etc) seasons. For the spring (tree season) 12 to 15 minims of dilution 4 may be sufficient for the protection dose

Patients receiving 15 to 20 minims of dilution 5 (equivalent to from 12,000 to 15,000 pollen grain units) are protected from any amount of pollen in the air, no matter how severely they have suffered in previous years, provided this dose is repeated once a week throughout the season

It would therefore be necessary for the general practitioner in order to successfully treat a case of hay fever or hay fever and asthma, to buy in the open market 15 to 20 c c of a 3 per cent concentrated glycerol-saline pollen extract for the respective season which is indicated by preliminary testing, and to obtain from a local laboratory five or more vials of sterile 10 c c physiological salt solution which would enable him to make his own dilutions

Continuation Treatment I have used the "continuation treatment" for the past four years This means to keep the patient under the maximum protective dose of pollen extract injected at the longest time interval throughout the year without inducing a reaction It is practical and desirable in the class of patients who can stand the maximum protective dose repeated every three, four, or five weeks without a reaction In about 5 to 10 per cent of patients the longest time interval, unfortunately, is not more than one week or ten days Every time the maximum dose is injected every ten days or two

weeks the patients get a reaction The maximum dose has to be constantly reduced by 1 or 2 minims so that at the following season the patient should have daily injections for two or three weeks to work him up to the highest protective dose Under these circumstances there is not much gained by the continuation method of treatment in this type of patient

Cardiac Failure

Report of a Case of Cardiac Decompensation of Fourteen Months Duration

By EDWARD J. STIEGLITZ, M.S., M.D., F.A.C.P., *Chicago, Ill.*

IT is most unusual for cardiac decompensation with severe edema to persist for as long as fourteen months. Cardiac failure and its associated phenomena have been repeatedly described and discussed, but the present instance permitted of long and careful study throughout the latter course of the decompensation, and revealed a number of most significant phenomena which warrant discussion.

REPORT OF CASE

The patient, a widow with one child, was first seen June 25, 1928, at which time she was 55 years old. The chief complaint was marked dyspnea, occurring particularly upon exertion, but noticeable even at rest or when talking. Pedal edema was also noted. A similar period of breathlessness and edema had occurred in 1924. The past history revealed frequent attacks of tonsillitis as a girl and considerable intoxication during the one pregnancy in 1898. The climacteric had been very abrupt in 1923. Her habits were good with the exception of a rather too liberal use of condiments. Exercise had long been extremely limited, both because of the low threshold of dyspnea and because of her obesity (her weight ranged about 200 lb., although the patient was but 4 ft. 11 in. in height). A lifelong history of migraine with typical cephalalgia and scotomata was elicited. The family history was significant in as much as both parents, one sister and two brothers had all died of

cardiac failure, probably of the hypertensive type.

Physical examination revealed a short obese elderly lady with moderately ashen subcyanotic facies. There were moist and crackling râles in the pulmonary bases. The left border of the area of cardiac dullness extended 12 cm. to the left, the right border was substernal. The second aortic sound was ringing in tone and accentuated, a very soft systolic aortic murmur was noted. The pulse was 98 at rest. The arterial tension was determined at 210/125 at rest, but fell to 180/120 upon minor exertion and to 152/100 upon the inhalation of amyl nitrite.¹ There was some pedal edema, dyspnea was marked upon very minor effort. The urine was normal.

The diagnostic summary made at this time noted the following:

- 1 Arterial hypertension with moderate arteriolar sclerosis
- Probable etiologic factors
 - 1 Hereditary influences
 - 2 Obesity
 - 3 Intoxication of pregnancy (1898)
 - 4 Frequent tonsillitis
 - 5 Oral sepsis
 - 6 Abuse of condiments
- 2 Hypertensive heart disease, Early decompensation
- 3 Obesity
- 4 Former migraine
- 5 Probable alveolar infection

The patient was advised to rest, stop the use of condiments and meat extractives; have roentgenograms made of her teeth; take dried digitalis leaves, gr. iss, t. i. d., and bismuth subnitrate, gr. x, t. i. d.^{2,4,5}

On July 2, 1928, the renal concentration test revealed a maximum specific gravity of 1024, 30 mg of albumin per hundred cc, a few casts, no sugar. The dyspnea was much improved, the arterial tension was 200/90. On July 18 a large dental abscess was demonstrated. The dyspnea had disappeared and the arterial tension was 184/85. By August 18 the arterial tension had fallen to 178/82, the pulse to 80. When seen September 17 the patient had had a severe shock as a result of a holdup and burglary. Since then the dyspnea had returned, the arterial tension had risen to 220/104. With similar digitalis therapy and continuation of the bismuth subnitrate, on September 26 the pulse was 86, dyspnea almost gone and the arterial tension 180/88. It was noted in October that she felt much calmer and less unstable emotionally, the arterial tension was then 162/84, and in November, 172/93. The abscessed tooth had as yet not been attended to. The dosage of bismuth subnitrate was reduced to gr x twice daily in October.⁶ During 1929 the patient felt quite well, complained only of dyspnea and some precordial pain upon exertion, during this year the arterial tension was observed to be 165/85, 166/90, and 175/90. The immediate outlook for the patient was rather encouraging.

On January 17, 1930, the patient was seen at home. She had been acutely decompensated with very marked pedal edema, severe breathlessness even at rest, orthopnea and cough for 2 or 3 weeks. The cardiac failure had been induced by a coryza with cough. At this time the pulse was totally irregular with almost alternating extra systoles and ranging about 120 in rate. The arterial tension was 170/100. From then on for 14 months it was a continuous daily struggle with the decompensation with a multitude of therapeutic agents, some of known and others of undemonstrated value. Certain of the clinical phenomena such as variation in weight, pulse, arterial tension, nausea and dyspnea are best illustrated graphically (figure 2).

The termination of this extraordinarily prolonged congestive cardiac failure was unusual—a sudden occlusion of the left femoral

artery caused gangrene of the left leg and such profound intoxication that the myocardium failed rapidly. Just prior to this fatal accident the patient was in better condition than at any time previously for a year. It is notable that throughout the prolonged decompensation with edema the urine was essentially normal. On March 9, 1931, the patient complained of sudden severe deep pain in both legs. This gradually became localized in the left leg and was not relieved by hot or cold packs or moderate sedatives. On March 10 it became necessary to administer 1/6th gr of morphine sulphate, the left leg was hot, of a blotchy red, and very tender. A cellulitis in the edematous tissue was suspected. By evening the pulse had risen to 110, the temperature to 101.4° F. On March 11 the arterial tension had fallen to 125/70, the pulse was 120, temperature, 102°, the patient was semicomatose, very cyanotic and the leg revealed large blotchy areas of deep cyanosis extending up to a sharp border at mid-thigh. By evening of the next day these blotchy areas had formed huge watery blebs which drained bloody serum profusely. At 7:30 P.M. on March 12 the patient was in deep coma and extremely cyanotic, the pupils were large but rigid, respirations were 44 per minute, temperature, 102° F, pulse, 110. At 9 P.M. the respirations were 48, pulse 114, arterial tension, 112/40, at 11 P.M. respirations were 50 and more labored, pulse 120, arterial tension, 104/35, at 12 midnight the tension had fallen to 98/32 and to 88/26 at 1 A.M. when the pulse was approximately 140 and totally irregular. The patient died at 1:42 A.M.

Necropsy. Only the essential observations will be recorded. The heart was very large and firm with most of the increase in size resulting from marked hypertrophy of the left ventricle. The right heart and the mitral valves were normal. The aortic valve was markedly stenotic and the cusps distorted. The valve ring was incomplete. Areas of calcification in the valve leaflets were quite extensive. The ascending portion and the arch of the aorta were smooth and glistening without defects. Several coronary vessels upon being opened revealed

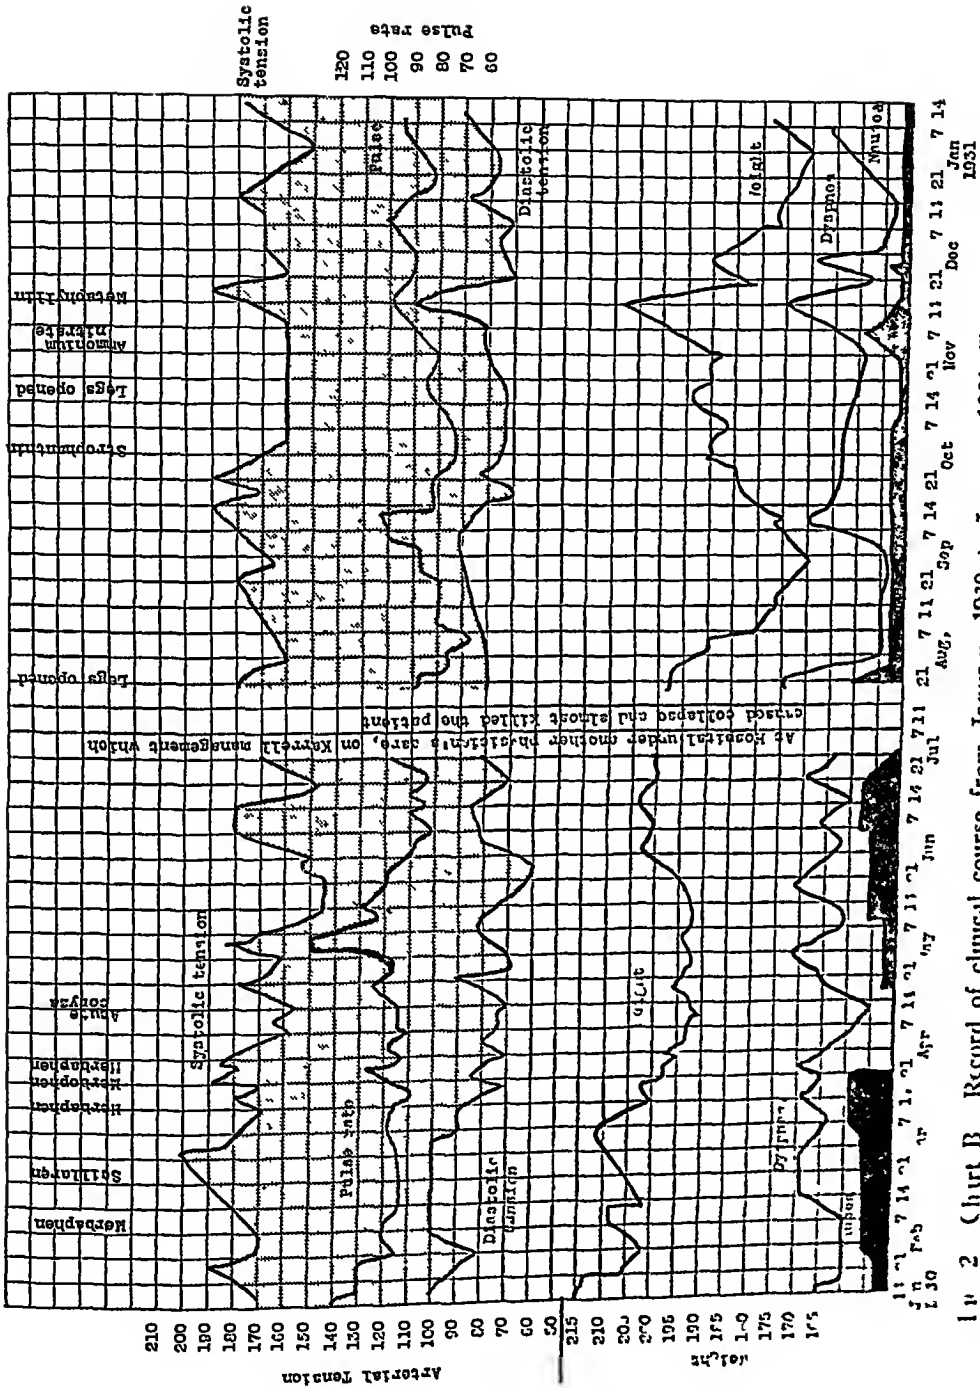

FIG 1 Chart A Course of the arterial tension under therapy with bismuth subnitrate prior to cardiac decamensation

102 2 Chart B Record of clinical course from January, 1930, to January, 1931. The average arterial tension, pulse and weight are recorded. The pulse pressure is represented by the shaded portion of the chart between the systolic and diastolic tensions. The degrees of dyspnea and of nausea are indicated along the base of the chart. Medication is recorded very incompletely, throughout this period. Digitals and appropriate sedatives were administered serially throughout. During the first two weeks of July the patient was under another physician's care and on that account the course from January to March, 1931, is not included.

moderate sclerotic lesions. The pericardium was normal, as was the endocardium with the exception of the aortic valves.

The kidneys were of normal size, the capsules stripped readily and cut surfaces appeared normal. The liver was hard, pale, and large. Surfaces made by cutting appeared grayish, as though cooked. The spleen also was engorged, somewhat enlarged, and firm. In the left femoral artery a rather fresh thrombus occluded the lumen at about the upper third of the leg.

Microscopic Findings. Throughout the tissues studied, marked and extensive arteriolar changes were seen. In the kidneys, heart and spleen, these were most marked. There was extensive thickening of the media, hypertrophy of the spiral smooth muscle fibers and some fibrotic changes in the intima of the arterioles and pre-capillary arterioles. Some medial thickening of the vasa vasa of the aortic adventitia was noted.

The renal parenchymal structures were essentially normal, both the tubules and glomeruli failed to reveal any appreciable damage despite the very prolonged severe edema.

The hepatic cellular strands were widely separated by edema, intense fatty vacuolization of the hepatic cells existed, especially in the central portion of the lobules. Hepatic fatty degeneration is characteristic of prolonged anoxemia. The Kupffer cells were more prominent than is usual. The portal canals and biliary ducts were essentially normal.

The intimal and medial portions of the aortic wall were normal. Arteriolar sclerotic changes were noted in the vasa of the adventitia. The elastic tissue was not disturbed, nor was the tunica elastica intima abnormal.

The heart muscle stained very poorly with phosphotungstic acid. The fibers were somewhat shortened and thicker than usual. The normal striations, however, were not appreciably altered. The nuclei of the cardiac muscle were pale, a few pyknotic nuclei were noted. The usual spindle shaped accumulations of sarcoplasm about the nuclei were not demonstrated. No evidences of acid or inflammatory lesions were found. Both the smallest and larger coronary ar-

teries seen on section revealed markedly thickened and hypertrophied medial layers—the medial muscular hypertrophy of hypertensive disease.

The aortic valve revealed extensive heavy calcification, chiefly at the base of the valve. The endothelium of the valve margin and sides was normally intact. Calcification, partially stratified, appeared along the valvular attachment, being densest along the center of the valve leaflet and in two bands below the subendothelial reticulum. A vasa vasa sectioned at the valve base revealed marked sclerotic narrowing with intimal proliferation. Such findings are in agreement with previous observations⁷ which indicate that such aortic valve calcification may be largely due to ischemia induced by impaired vascular supply.

COMMENT

The above brief resumé of the course of this unusually prolonged instance of cardiac failure merely outlines the sequence of events and does not touch upon the profound significance of a number of phenomena and the related therapeutic problems.

The comparative value of various therapeutic agents was demonstrable because of the opportunity for prolonged observation. Certain aspects of the complex problem of edema of circulatory origin are worthy of emphasis. The behavior of the arterial tension, and particularly the pulse pressure, deserves consideration. The most unusual termination by thrombosis of a peripheral artery in an edematous extremity warrants recording.

At the very onset of the cardiac decompensation it was made clear that medication intended to reach and to affect the heart had to be administered in such a manner that delivery to the site of action was assured; medication was by intravenous injection. Digitalis

FIG 3 Kidney, magnified 77.5 diameters, hematoxylin and eosin stain. The tubular and glomerular structures are essentially normal. The medium sized artery shown on the right reveals extensive thickening of the media and some intimal proliferation.

FIG 4 Kidney, magnified 154 diameters, hematoxylin and eosin stain. The normal appearance of the tubules and glomeruli are well demonstrated here, there is some edema of the stroma.

FIG 5 Liver, magnified 232.5 diameters, phosphotungstic acid, hematoxylin stain. Fatty degeneration of the parenchymal hepatic cells. Increase in size and depth of stain of the Kupffer cells of the sinusoids, notable in the center of the field.

FIG 6 The myocardium, pericardium and part of a coronary artery, magnified 77.5 diameters, hematoxylin and eosin stain. Thickening of the medial and intimal coats of the arterial wall is visible.

administered by mouth failed to have any effect upon the pulse rate early in the course of decompensation when there was extensive intra-abdominal edema and ascites and when the edema was increasing. It must be realized that in the presence of extensive edema the alimentary absorption of digitalis, or any other drug is greatly interfered with^{8, p. 182}. The gastro-intestinal tract is edematous, as are the other tissues, and apparently most of the drug is retained in the edematous tissue^{8,9}. Subcutaneous administration into edematous tissue is similarly inadequate^{10,11}. It is necessary that digitalis, and similar acting principles actually be delivered to the heart,¹² the site of action. Digitalis, although strengthening the force of cardiac systole, does not cause a rise in arterial tension¹³. The diastolic pressure is usually lowered by the improved efficiency of the circulation, which produces increased renal secretory efficiency and greater elimination of toxic waste. Improvement in the circulatory efficiency likewise results in more effective cerebral circulation. As the prime purpose of digitalis medication is to slow the pulse,¹⁴ it should be administered in adequate dosage. The danger of cumulative effects of digitalis has been exaggerated¹⁵. Most patients suffer far more from inadequate than from excessive administration^{16,17}.

Toxic effects of overdosage of digitalis are usually first manifest as nausea and vomiting, later diarrhea, cephalalgia and disturbances of vision²⁸ may appear, with heart block occurring in instances of marked overdosage¹⁸. The nausea, vomiting and diarrhea have been attributed to reflex action

from the heart, not to direct gastro-intestinal irritation^{19,20,21}. The secondary toxic effects of squill or strophanthin are similar. In the present instance of cardiac decompensation it was repeatedly observed that preparations of squill ("Scillaren," Sandoz) created more nausea than did digitalis. Strophanthin, likewise produced more nausea than digitalis. For many months the patient either was distressingly dyspneic because of relatively inadequate digitalization or she was emphatically nauseated. Neither squill nor strophanthin preparations revealed any clinical advantages over digitalis throughout the course of the decompensation.

Because of the marked disadvantage of nausea induced by adequate digitalization, during the last several months of the cardiac decompensation, coramine, a relatively new synthetic cardiac and respiratory stimulant, was given a trial. It was found to be equal to digitalis in effectiveness in maintaining a slower pulse and caused no nausea or gastro-intestinal distress²². Coramine was well tolerated and was efficient in controlling the severe and distressing dyspnea and orthopnea²¹. Coramine is synthetically produced, its chemical composition is pyridine-beta-carbonic acid-diethylamide²⁴. There was no evidence of cumulative effect, nor was there any indication that tolerance to the drug was being acquired²³. Coramine is said not to depress the auriculo-ventricular conductivity as does digitalis⁻⁶.

Not only is it subjectively distressing for the patient to be semi-continuously nauseated, but it is objectively most undesirable because nausea so

greatly interferes with proper nutrition and caloric maintenance. This was repeatedly demonstrated in the present instance whenever nausea and anorexia prevented the patient from taking an adequate diet, the cardiac insufficiency was augmented. It has been emphasized by Smith, Gibson and Ross²⁷ that an adequate glucose intake is essential for recuperation of injured myocardial tissue. For this reason alone it is most important not to aggravate the anorexia of the very sick patient. As it is most illogical to anticipate active reparative rehabilitation of injured tissues under conditions of tissue undernutrition or inadequate oxygen supply, maintenance of an adequate hemoglobin content of the blood is of similar significance.

The behavior of the pulse pressure during this prolonged period of cardiac inadequacy was most instructive. It was noted (see figure 2) that whenever the cardiac efficiency declined there occurred a marked depression of the diastolic tension with a corresponding increase in the pulse pressure. These changes occurred frequently whenever exertion, excitement, transient coryza or excessive fatigue further exhausted the myocardium as evidenced by greater rapidity of the pulse rate, greater dyspnea and gains in weight due to increasing of the edema. It has long been taught²⁸ and correctly, that diminution of the myocardial efficiency results in reduction of the systolic tension and pulse pressure and that such reduction is of ominous prognostic import. The pulse pressure may be considered a rough measure of the stroke volume²⁹ which is ordinarily reduced in cardiac exhaustion.

The pulse pressure usually falls in myocardial exhaustion with tachycardia but is increased in thyrotoxic tachycardia³¹ in proportion to the elevation of the basal metabolic rate, and the increased cardiac volume output. However when the aortic valve is incompetent, the diastolic tension is lowered and the pulse pressure markedly increased. In this patient aggravation of the cardiac inadequacy led to further left ventricular dilation and dilation of the aortic ring. The fact that the aortic valve was calcified was unknown at the time these observations were made. As pointed out by Christian³² calcification of the aortic valves is most frequently undetected clinically when hypertension co-exists. Such aortic valvular calcification is more frequent in males, is very slowly progressive and usually asymptomatic until cardiac decompensation occurs; excessive left ventricular enlargement is the rule as in the present instance. Of 22 cases mentioned by Christian, in 19 the Wassermann was negative; rheumatic infection early in life, as in the present case, is the predominant etiology. Characteristic of such lesions is the asymptomatic course prior to the final and usually brief decompensation³².

Although diminution in pulse pressure is the usual rule during cardiac decompensation and should serve as a warning of impending disaster³ the reverse may occur because of dilation of the aortic ring and the creation of a state of aortic incompetence. The unwary may be led astray if this is not kept in mind. The presence of murmurs in the aortic area assist but do not make sharply definite a diagnosis.

of aortic regurgitation induced by dilation during cardiac decompensation irregular murmurs all over the precordium both systolic and diastolic in time, obscure their significance. Reduction in diastolic tension *under these conditions* was of ominous prognostic import although the more usual phenomenon is diminution of the systolic arterial tension without great change in the diastolic tension.

Evaluation of the prognosis in the present instance was based upon a number of important considerations, no one factor may be utilized as the sole criterion for prognostication.¹ Of importance are the following factors: (1) history of previous decompensations, (2) the etiologic background of prolonged extensive hypertensive disease, (3) the evidence of aortic insufficiency, (4) the age of the patient, (5) the marked obesity for many years, and (6) the failure of the heart to respond adequately to energetic digitalization. Repeated attacks of cardiac failure reduce the cardiac reserve with each decompensation, some of the surplus or reserve is destroyed with each struggle for returned compensation and a smaller and smaller margin of safety remains. As many as eight instances of cardiac decompensation in the same patient have been observed.⁸

The etiologic background of prolonged and extensive hypertensive disease affected the prognosis adversely. It may be stated as a dictum of clinical experience that in prolonged hypertensive arterial disease myocardial injury exists *a priori*.^{3, p 157} The myocardium is embryonically, anatomically and functionally a specialized portion

of the arterial media, (the site of injury and change in hypertensive disease) and is therefore open to the same sources of injury as initiate the original vascular disease. In addition to this myocardial injury is the factor of fatigue, engendered through excessive and unremitting work in overcoming the high peripheral resistance. Myocardial nutrition is impaired by the malcirculation resultant from coronary arterial disease, such ischemic asphyxial intoxication is a most significant factor. The paroxysms of precordial pain in angina pectoris are apparently the result of cardiac anoxemia.³³ This anoxemia is enhanced by anemia. In the present instance, therefore, it was amply justifiable to assume extensive myocardial injury independent of the valvular disease and myocarditis possibly initiated by the frequent attacks of tonsillitis during the patient's later childhood. The presence of the aortic diastolic murmur, evidencing an aortic regurgitation, further darkened the prognosis. The age of the patient precluded any of the phenomenal recuperative powers of youth and the obesity placed a greatly increased burden upon the faltering myocardium which failed to respond to the intensive digitalization promptly induced at the beginning of the present decompensation. It was primarily in this respect that this third and last attack of cardiac decompensation differed at the onset from the second attack observed 18 months previously. This failure to respond could only indicate one thing: that the myocardium was now most thoroughly exhausted and had almost no reserve to fall back upon.

Aside from the distressing dyspnea

and orthopnea the severe edema or anasarca was the most distressing clinical phenomenon. Throughout the course of the terminal illness the edema was profound, most of the time the patient retained from sixty to eighty pounds of edema fluid. A number of most significant considerations in this condition warrant discussion.

Edema may be defined as any undue accumulation of fluid in the tissues and tissue interstices. For many years it was thought that such accumulation was due to the failure of the kidneys to adequately secrete water. This is not the case, however. The oliguria results from the failure of the renal tissues to receive free water for secretion as urine, the water being held by the tissues. The correction of the earlier erroneous conception, has been due largely to the significant researches of J. Loeb,³⁴ Fischer,³⁵ L. Loeb,³⁶ Aldrich and McClure,^{8,10} Andrews³⁷ and many others. To attempt any comprehensive discussion of edema here is impossible. For our clinical purposes, however, a number of salient conceptions need emphasis. The mechanism of the production of cardiac edema is probably very similar to that of toxic or so-called renal edema; in both instances edema being due to tissue intoxication, alteration of the hydration capacity of the tissue colloids and increased avidity of the tissues for the accumulation and retention of water. Whether these changes be due to circulatory inadequacy as in congestive heart failure, or to intoxication in renal disease is relatively immaterial for our present purpose.

Edema has come to be considered a protective mechanism, possibly an at-

tempt on the part of the tissues to dilute and retain toxic noxa in relatively unimportant structures and thus spare the vital parenchymatous organs. It is notable that the earliest and greatest accumulations of edema fluid are in the skin, extremities and serous cavities, whereas absolutely essential structures such as the heart, kidneys, brain and liver are involved to but a minor degree. In part this may be due to the much greater expansibility of these sites of predilection, in part it may be considered teleologic evidence of the conception that edema is a protective mechanism. Nephritic children become profoundly intoxicated and may develop uremic convulsions if edema is rigidly repressed by deprivation of adequate fluid intake. Convincing evidence makes necessary a change in our original definition of edema in the clinical sense: edema is any undue accumulation of fluid in the tissues or tissue interstices due to changes in the tissues, causing retention of fluid by them and *associated with the accumulation of toxic matter*. Edema fluid is toxic.³⁷ The toxicity of the edema fluid was repeatedly and conspicuously demonstrated in the present instance of congestive heart failure. It is inconceivable that such extensive accumulations of fluid should persist for many months without being laden with toxic metabolic products.

Whenever diuresis was successfully, although temporarily, induced by any method the patient promptly became profoundly intoxicated: the pulse rate rose, dyspnea increased, anorexia, nausea and vomiting became more pronounced, cyanosis deepened and the patient felt intoxicated as though by an

infective process. The more rapidly the edema fluid was shifted from the tissues into the circulation the more marked was the intoxication. This was strikingly manifest during an attempt at edema reduction by Karrell management³⁸ with severe restriction of fluid intake (200 cc milk four times a day and nothing else), undertaken by another physician. This procedure almost killed the patient, the severe restriction of fluids led to such a profound intoxication that the patient became comatose. Only through the prompt introduction of fluids was disaster prevented at that time.

Thus the problem of the treatment of edema is not merely the problem of removing the water of the edema fluid, but consideration of the removal of the very toxic solutes is essential. That these toxic solutes are a real menace is incontestable. Mere transfer of the toxic fluid from the tissue spaces into the circulation is most detrimental, this places the noxa where great damage can be done to the essential parenchymatous structures. On one occasion, Nov 13, 1930, in the present instance, the patient lost 19 lbs in 16 hours by diuresis induced by intravenous metaphyllin. This rapid liberation of fluid so profoundly intoxicated the patient that she became semi-comatose and the arterial tension rose to 240/130, causing a transient hemiplegia and aphasia which persisted for 36 to 48 hours.

Such intoxication represents a detriment which far outweighs the benefit of weight reduction through the loss of fluid. It appears immaterial by what medication diuresis is induced, theobromine, theocalcin, metaphyllin, euphyllin, potassium salts, calcium glu-

conate,⁴³ calcium chloride and ammonium nitrate^{39,40} were all used in connection with digitalis, scillaren or strophanthin. Small doses of dessicated thyroid⁴¹ with coramine (no nausea) produced a more persistent and less intoxicating diuresis. Hydrogogue catharsis, as with elaterin, caused marked exhaustion and debility, the loss of fluid was but temporary.

It is of essential importance in the treatment of edema that everything possible be done to assist in cardiac repair and rehabilitation for the primary factor in the causation of such edema is the circulatory failure. Retardation of the exhausting rapid pulse by digitalis or related drugs is of the greatest importance. Adequate nutrition, especially with carbohydrates, is necessary. Oxygen debt may be reduced by the use of an oxygen tent; the diminution in cyanosis and anoxemia is often remarkable.⁴² It is in the advent of these direct cardiac measures being inadequate in reduction of the edema that the other methods of attack must be utilized.

Removal of edema fluid by mechanical means permits of partial relief of the anasarca without liberation of the very toxic debris into the circulation. Should extensive accumulation of fluid occur in the serous cavities, this is readily accomplished by paracentesis or repeated thoracentesis. In the present instance however the edema was dependent, the patient's legs were huge and of almost boardlike hardness up to the mid-thigh. It was only occasionally that evidence of intra-abdominal accumulation of fluid could be elicited, the thorax and upper extremities were at no time edematous. On

two occasions incisions were made in the legs, on either side of the edematous ankles, with most gratifying drainage after the first procedure. After these incisions (about 10 cm long and 3 cm deep into the subcutaneous tissue) had been made, the weight of the patient fell from 202 lbs to 172 lbs in three weeks, losing 20 lbs in the first five days. This was the only occasion when such marked weight loss (edema loss) was not accompanied by the severest form of intoxication. During and following this period the patient felt unusually well and energetically strong.⁴² Gradually, however, because of the persistence of the circulatory inadequacy, the extremities became more and more edematous again and a second attempt on Oct 14, 1930, to produce free drainage resulted in a temporary loss of approximately 10 lbs in 10 days. On this second occasion drainage was scant and slow, the edema had become more firmly "fixed" in the intoxicated tissues and was retained with great tenacity; the tissue thirst^{3,6,9,10} had become more marked. Such surgical intervention in extensive edema of the extremities, of course, does not alter the hydration capacity of the tissue colloids so as to cause them to give up their bound water, nor does it in any way effect the etiologically significant malcirculation, except inasmuch as there is reduction of the mechanical obstruction due to the edema. Therefore the limitations of such mechanical drainage are notable; no physiologic diuretic effect is to be anticipated. However, the administration of the xanthin diuretics greatly increases the flow of serum from the vessels and it is felt that this is most

desirable. The one great advantage of such a route of elimination for the edema fluid is that the toxic debris and "edema toxins" are *not thrown into the circulation*; diuretic medication to the tissues liberates more of the fluid and thus the flow is enhanced.

Three important and often neglected clinical aspects of the problem of circulatory edema were repeatedly emphasized during this long struggle: edema fluid is poisonous; edema fluid caused profound intoxication when thrown rapidly into the circulation; concentration of these toxins by water deprivation increases the intoxication to a dangerous degree and for this reason the patient should be protected by an adequate fluid intake during diuresis and the subsidence of edema. Water itself is probably the safest diuretic if used with judgement and discretion. If edema is considered a protective mechanism, which we believe to be the case, the objective of therapy should not be limited to removal of the water alone but should consider of primary importance the removal, or the rendering innocuous, of the very toxic solutes in such fluid. Very rapid diuresis is dangerous, particularly in instances of edema of long duration. Dilution of the fluid by liberal water intake is desirable.

It is most important to realize that both clinically and pathologically there was no evidence of notable renal disease in the present case. Frequent analyses of the urine revealed a few casts, some epithelial debris, from 10 to 30 mg albumin per hundred cc (sulphosalicylic acid method), no sugar or pus. Anatomically at autopsy the renal tissue showed little or no parenchymatous

change both grossly and microscopically. The pathologic picture was that of long standing hypertensive arterial disease with arteriolar sclerosis,³ but no nephritis. Secondary injury, attributable to the hypertensive disease, was primarily cardiac. The unusual terminal accident of thrombosis of the femoral artery deserves a word of comment. What is most extraordinary is that arterial occlusion in an edematous extremity does not occur more often. So far as our search has gone we have been unable to find any other reported instances of such termination in congestive cardiac failure. The origin of the thrombosis was undoubtedly embolic, probably from the diseased aortic valve leaflets. It is but a very remote possibility that the surgical wounds about the ankle had anything to do with the arterial occlusion; they were clean and free from infection throughout the course and the occlusion occurred from above, not below. Occlusion of the femoral artery does not necessarily result in gangrene of the extremity as normally the collateral circulation suffices to maintain adequate nutrition, in the present instance, however, the

severe and prolonged edema markedly impeded the circulation and did not permit of sufficient oxygenation. Although the original prognosis had never been good, such an accident must inevitably mark the beginning of the end.

SUMMARY

In an unusually prolonged instance of congestive cardiac failure with extensive edema a number of pertinent clinical phenomena have been studied and reported. Clinical evaluation of a number of therapeutic agents is made. The behavior of the arterial tension during decompensation is discussed and the bases for the evaluation of the prognosis considered. Certain significant aspects of the clinical problem of edema in cardiac decompensation are emphasized. Another instance of aortic stenosis with calcification of the aortic cusps, recently described by Margolis and his associates⁷ and Christian³² as a distinct clinical entity, is recorded. Report is made of the unusual feature of termination by occlusion of the femoral artery in an edematous extremity.

Two Ways of Dealing with Unqualified Medical Sectarians

“THERE are two ways of dealing with the problem constituted by the existence of unqualified medical sectarians. One is the non-legal, and involves striking at the cultists by removing the causes which lead people to go to them. The second involves the legal suppression of the sectarians. The first approach, being the more fundamental, is in the long run the simpler and more effective. The major factors responsible for the growth of cults are credulity, ignorance and superstition on the part of the public. It is obvious that if the cults are to be eradicated, these failings must be remedied and people must learn more about the make-up and functioning of the human body. Furthermore, it is only as people gain an intelligent understanding of the human body that they can be led to understand the necessity for legal suppression of unqualified healing practitioners. To the extent that certain deficiencies in medical practice have contributed to the rise of present-day sects, the removal of those deficiencies will aid in the eradication of the sects.

“The second way of eliminating unqualified sectarians is through laws regulating the healing art. At the present time in the United States the legislative regulation of the healing art—regulation designed to protect the public from unqualified practitioners—is not accomplishing its acknowledged purpose. All it does is to maintain high standards for one group of practitioners. Quite illogically, it also sanctions the existence, on a lower plane of qualifications, of many thousands of poorly trained practitioners. Manifestly if the public is to be adequately protected, there must be a single minimum standard of qualifications for all healing practitioners.”

From *The Healing Cults—A Study of Sectarian Medical Practice Its Extent, Causes and Control* By LOUIS S REED, Ph D. The Committee on the Costs of Medical Care, 910 Seventeenth Street, N W, Washington, D C (Abstract of Publication No 16)

Generalized Myositis Fibrosa

By EDWARD H. SCHWAB, M D ; PAUL BRINDLEY, M D , MEYER
BODANSKY, Ph D , and TITUS H. HARRIS, M D , F A C P ,
Galveston, Texas

LOCALIZED disease of the muscular system of an acute or subacute nature, commonly designated muscular rheumatism, fibrositis, myositis, or myalgia, is of very common occurrence. Pemberton¹ has remarked that it is probably one of the most widespread and frequently occurring conditions to which human beings are subject, excepting mild infections of the upper respiratory tract. Quite in contrast to the above statement is the fact that inflammatory muscular diseases of a generalized nature, either acute, subacute, or chronic, are exceedingly rare. In the acute and subacute group four types are recognized: primary suppurative myositis which is only occasionally generalized, myositis, a result of *Trichinella spiralis* infestation, dermatomyositis, and polymyositis hemorrhagica which is probably a form of the latter condition. In the chronic group there are three types: the chronic form of dermatomyositis; myositis ossificans progressiva; and primary myositis fibrosa. The latter condition, primary

myositis fibrosa, is presumably the rarest of all types, there being only four typical cases reported in the literature, with perhaps as many doubtful or atypical ones.

RÉSUMÉ OF THE LITERATURE

Janicke² in 1895 reported the first typical, authentic case of generalized myositis fibrosa. Prior to this time Gies³ (1879) and Kreiss⁴ (1886) each described a case of myositis fibrosa which, however, can hardly be regarded as typical since the extent of the involvement of the muscles was small, the lower limbs only being affected, but particularly because there was also involvement of the overlying skin. Gowers⁵ (1899) in a lecture on polymyositis described an unusual case which has been designated as a case of myositis fibrosa in a recent review of the literature.⁶ In this case the intense pain at the onset of the illness, the early appearance of foot drop, and the loss of deep reflexes leads us to believe that the condition was perhaps a peripheral neuritis of widespread distribution with secondary atrophic changes in the muscles. Moreover, histological evidence to support the diagnosis of myositis fibrosa is lacking. The case of Batten⁷ (1904) was the first to be accompanied by a

Received for publication, November 7, 1931.

From the John Sealy Memorial Research Laboratories, the Departments of Internal Medicine and Pathology, School of Medicine, University of Texas, Galveston, Texas.

detailed pathological study. In 1923 Burton, Cowan, and Miller⁶ reviewed the literature and contributed an additional case. Hoover⁸ (1924) has briefly described a case which appears to be quite typical; however, it was not proved by histological examination of tissue. The same author reported a case of dermatomyositis (case 3) which is somewhat atypical for that disease in that the characteristic skin changes were not present and which, to the present writers, seems to resemble myositis fibrosa. Rosenstirn⁹ in his extensive review of the published cases of myositis ossificans progressiva found two cases which he thought had been erroneously diagnosed and which had extensive fibrous changes in the muscles rather than ossification. The first of these (Lexer,¹⁰ 1895) was characterized by a generalized distribution throughout the muscular system of fibrous nodules containing calcareous material. The second case is that reported by Krause and Trappe¹¹ (1907), and was thought by Rosenstirn to be a case of myositis fibrosa. In this case, the multiple nodules, many of which had undergone softening, and the extensive changes present in the skin would cast considerable doubt as to the validity of Rosenstirn's correction. Perhaps the most that can be said of both cases is that if they belong to this group they are exceedingly atypical.

ETIOLOGY

Little if anything is known concerning the etiology of this rare disease. It seems rather likely that it is related pathogenetically to the localized myositides in that the histological picture of the muscle tissue in general-

ized myositis fibrosa does not differ greatly from that in the later stages of fibrositis. If so, the disease may be added to that already very large group designated as the rheumatoid or arthritic syndrome. Batten⁷ suggested the possibility of this condition being allied to myositis ossificans progressiva largely because his case exhibited microdactylia of the large toes. Several facts concerning the two diseases renders this relationship not impossible. Ossification of muscle tissue in nearly all cases is preceded by a myositis. According to Rosenstirn,⁹ the primary pathological change in myositis ossificans is capillary hemorrhage, and Llewellyn and Jones¹² have shown that the early change in fibrositis is a dilation of the small blood vessels and capillaries, with not infrequently minute hemorrhages.

CASE REPORT

O. E., a negro boy, 14 years of age, a student by occupation, entered the John Sealy Hospital, January 3, 1929, complaining of stiffness of the entire body and pain in the chest.

Family History. Mother and father living and well, age 51 and 57, respectively. Five brothers and six sisters all living and well, the oldest being 33, the youngest 10 years of age. Negative history for syphilis, tuberculosis, and cancer.

Past History. Born at full term, normal delivery, the eighth child. He began walking at the age of 2. He was somewhat slow in talking and always stuttered badly. At the age of 7 he started to school and seemed to make normal progress, attaining the fifth grade at the onset of his illness. During childhood he was unusually healthy and the only disease which he had had was measles at the age of 9, from which he made an uneventful recovery. At the age of 10 he helped on the farm picking out chickens. He was regarded by his family as being a perfectly normal child except for

the stuttering, until the beginning of the present illness

Present Illness About one year prior to entry into the hospital he noticed a dull aching pain in the upper part of the chest. This symptom was present more or less continuously and was not intensified by respiration. He consulted a physician who gave him some medicine which caused the pain to disappear. At about the same time his mother noticed that he was not as "pert" as usual and that he seemed to move rather slowly and deliberately. However, he continued to go to school and to do odd jobs around the house. A few weeks later he noticed a peculiar stiffness in his hands which made it difficult for him to perform the finer movements without clumsiness. This stiffness slowly but progressively became worse. Four or five weeks after the recognition of the stiffness of the hands he noticed a similar state of affairs beginning in his legs which seemed to largely involve the knees and which interfered to some extent with walking. In September, seven months after the onset of his illness, he started to school as usual, but was unable to play with the other children as he had previously done because of clumsiness in walking and running. While doing calisthenics he noticed that he was not able to bend over as far as the other children and that his back seemed to be stiff and rigid. His appetite had remained good throughout his illness and as far as he could tell he had lost no weight. There was no constipation, nocturia, or polyuria. At no time during his illness had there been any fever or pain in his muscles or joints.

Physical Examination The general appearance was that of a dull, apathetic negro boy of about 15 years of age. He stuttered badly when he attempted to speak. Height, 5 feet and 9 inches, weight 117 pounds, calculated ideal weight, 140 pounds.

The face was non-expressive. No cervical adenopathy was present. The skin immediately surrounding the mouth was lighter in color than that of the face but no indentation was present. The conjunctivae and sclerae were pale. The lips were in good con-

dition. The tonsils were present, moderate in size and innocent in appearance.

The chest was of the asthenic type. Some deepening of the supra- and infra-clavicular fossae was noted. There was very little movement of the chest wall during respiration, breathing being entirely abdominal in character. Palpation and percussion resulted in negative findings. On auscultation the breath sounds were puerile, no râles were heard and the transmission of the spoken voice was normal throughout.

The cardiac impulse was diffuse in the third, fourth and fifth interspaces to the left of the sternum. No enlargement was made out by percussion. The heart sounds were loud and distinct. No murmurs were heard. The pulmonic second sound was markedly accentuated. The pulse rate was 88 and regular, the blood pressure, 116 mm Hg systolic, and 70 mm Hg diastolic. There was no evidence of arteriosclerosis in the peripheral vessels.

The abdomen was scaphoid. The liver and spleen were not palpable and there were no masses or areas of tenderness. Rectal examination was negative. The genitals were normally developed. Both testicles were present in the scrotum. The prostate was normal in size, shape, and consistency.

The skin over the entire body was apparently normal except over the wrists and hands, where it was shiny in appearance and seemed somewhat thinner than normal. However, it was pliable and not bound down to the underlying tissues. The hair was normally distributed over the body.

Practically all the muscles of the body, but some more than others, seemed to be indurated. To the palpating hand they imparted the sensation of being firmer and stiffer than normal, and not unlike a sand-bag. The muscle volume was fairly well preserved, with the exception of the deltoid and pectoral muscles which showed considerable atrophy. None of the muscles were painful either on palpation or movement. They seemed to have lost much of their normal elasticity with resulting limitation of movement. All movements of the face and lips were well performed. The masticatory muscles were involved to such an extent that when the mouth was opened a

widely as possible the distance between the incisor teeth was only 3 cm. The sterno-mastoid muscles were only slightly involved. The arms could be abducted only to an angle of about 60° with the chest wall and at that point further abduction was prevented by tightening of the tendons of the pectoral and latissimus dorsi muscles (figure 1a). Extension of the elbows was possible only to an angle of about 160° because of shortening of the biceps muscle (figure 1b). Flexion of the elbows was not interfered with. Passive movements of the wrists were easily performed within a certain range but were abruptly checked by a tightening of the flexor and extensor tendons. The fingers were held in a semiflexed position and any attempt to extend them fully was thwarted almost immediately by tightening of the flexor tendons. The muscles of the trunk and lower extremities were uniformly involved. The knees could be flexed only to an angle of approximately 100° due to shortening of the quadriceps femoris muscle (figure 1c). The strength of all involved muscles was definitely impaired. There was a very feeble grip of either hand.

The gait was somewhat spastic. All the cranial nerves were normal. Fundus examination was negative. All deep and superficial reflexes were present and equal. There was no disturbance of sensation anywhere in the body nor was there any paralysis.

Laboratory Examinations. The urine was entirely negative. There was a slight secondary anemia present. Hemoglobin, 75 per cent (Sahli), red blood cells, 4,050,000 per cu mm, white blood cells, 12,000 per cu mm, with essentially a normal differential count. The blood and spinal fluid Wassermann tests were negative. Blood chemistry: total non-protein nitrogen, 30 mg, urea nitrogen, 11 mg, uric acid, 57 mg, creatinine, 13 mg, and sugar (fasting) 91 mg, per 100 cc of blood. Spinal fluid examination was entirely negative. The basal metabolic rate was plus 14. The phenolphthalein excretion was 55 per cent in two hours. An electrocardiogram showed sinus rhythm with low voltage in all leads with slurring of the Q-R-S complexes. All T waves were upright. X-ray examination

of the teeth, wrists, joints of the fingers, elbows, sella turcica, and skull were entirely negative.

Course in the Hospital. On admission the patient was afebrile but a week later he began to show a slight afternoon rise in temperature, 99° to 99.6° F. The pyrexia continued and gradually increased in degree. Two weeks later he complained of attacks of dyspnea which were especially troublesome at night and which were often accompanied by a dull aching pain over the precordium. He began to lose weight, 2 to 3 pounds a week. On several examinations of the chest it was now noted that moist râles were present in both apices. After a stay in the hospital of about two months the elevation in temperature became a more or less constant feature, usually reaching 101° F, in the afternoon. A tachycardia was constantly present. The physical signs in the chest became more pronounced and an X-ray study revealed evidence of an infiltrative lesion in both apices, which was thought to be tuberculous in nature. There was no cough or expectoration and as a result sputum could not be obtained for examination. Weakness became a prominent symptom and eventually he was confined to bed. Dyspnea was evoked on the slightest exertion. His condition gradually became worse and death occurred three months after admission.

Autopsy. Necropsy was performed five hours after death. Rigor mortis was present. On incising the pectoral and abdominal muscles they appeared to be lighter in color than normal and to cut with increasing resistance. The heart weighed 280 gm. The valves were normal with the exception of the pulmonic leaflets which showed slight fenestration. The myocardium was abnormally light in color. The left lung contained an area of consolidation in the lower portion of the upper lobe and the overlying pleura was dotted with greenish white nodules measuring 1 to 2 mm in diameter. Section of this region of the lung revealed multiple areas of caseation. The right lung was apparently normal. The hilar nodes were enlarged and on section showed multiple greenish areas. The mediastinal nodes were likewise enlarged and on section were greenish.

Fig. 1. Illustrations of the impairment of muscle function, (a) showing maximum extension of elbows, and (b) maximum flexion of elbows.

ish in color with their central portions semi-fluid in consistency and of a turbid, greenish color. The liver and spleen were larger than normal, their respective weights being 1860 and 230 gm. There was one small area of caseous necrosis in the spleen. No abnormal changes were noted in the kidneys, stomach, adrenals, pancreas, intestines, testicles, and urinary bladder. Permission was not granted for examination of the brain and spinal cord.

Microscopic Findings The consolidated area in the left lung and the lymph nodes of the hilus and mediastinum showed evidence of an acute tuberculous process in the form of miliary and conglomerate tubercles along with liquefaction necrosis, especially in the nodes. The myocardium was abnormal in that there was a slight increase in the size of the fibers with a more granular cytoplasm. There was also a slight increase in fibrous tissue and in this were found a few scattered mononuclear, inflammatory cells. Parenchymatous degen-

eration and hyperemia were noted in the kidneys.

The histological examination of the *voluntary muscles* resulted in extremely interesting findings. Prior to death, specimens were obtained from the soleus and quadriceps femoris muscles. At autopsy tissue was procured from the following muscles: rectus abdominis, psoas, iliacus, pectorals, sartorius, diaphragm, intercostals, and deltoid. On gross examination the muscles were distinctly lighter in color and had a somewhat greyish tint. On palpation they were firmer than normal and on section cut with increased resistance.

Microscopically, degenerative, inflammatory, and fibrous tissue changes were found (figures 2 and 3). The three types of change were present in

FIG. 2 Longitudinal section of the rectus abdominis muscle. Note the increase in size of the individual fibers, their complete destruction in some areas, and the infiltration with inflammatory cells.

all muscles, varying, however, in degree. In both longitudinal and cross sections the individual muscle fibers exhibited great variation in size, some of them appearing larger than normal, whereas others were reduced to as much as a fifth their normal diameter. In many fibers, all striations had disappeared while in others the longitudinal striations only were present with loss of the transverse ones, and *vice versa*. Hyaline degeneration and hy-

dropic infiltration were commonly noted. Scattered throughout the muscle tissue were varying numbers of inflammatory cells and in certain areas they formed definite collections. In such areas the muscle tissue had undergone more or less complete degeneration. By far the larger number of these cells were of the lymphocytic group. A small number of plasma cells were present along with large endothelial cells and fibroblasts. Only

Fig. 1. Cross section of the sartorius muscle. Note the hyaline degeneration and the collection of inflammatory cells.

an occasional polymorphonuclear cell was noted. Variable amounts of new fibrous tissue were found in different muscles, and constituted approximately 10 per cent of the muscle volume. This change was most marked in the iliacus, quadriceps femoris, rectus abdominis, and deltoid muscles. None of the fibrous tissue had reached the adult type. Microscopic study of the peripheral nerves revealed no departure from the normal. A more detailed description of the histopathology will be presented in a future communication.

THE CLINICAL PICTURE

A summary of the clinical findings in the reported cases is outlined in table 1. Age and sex apparently play no part as predisposing factors in the causation of this disease. The youngest case occurred in an infant of 9 months, whereas the oldest was in a man of 48 years. Males and females appear to be equally affected. Our case is the only one reported occurring in the negro race.

The onset of the disease is insidious but once begun seems to progress fairly rapidly, the process requiring only a few months to cause definite impairment of muscle function. Batten's⁷ case required 5 years to reach an advanced stage, whereas Hoover's⁸ case was rendered an invalid in two years. In the case here reported the process developed more rapidly, producing invalidism in about 9 months. Previous diseases or infections were in some instances incriminated as factors in the causation of the muscular condition. The case of Burton, Cowan and Miller⁹ had had a pyelitis prior to the onset of symptoms and also frequent

sore throats. In their case it is also interesting to note that there were exacerbations with each pregnancy. The questionable case reported by Gies³ had a carbuncle on the back a year previously. Our case apparently had a quiescent pulmonary tuberculosis at the time of admission.

The presenting symptom in practically all of the cases was a feeling of stiffness in the extremities associated with inability to perform voluntary movements without clumsiness. This symptom became progressively worse as the disease advanced, ending eventually in marked limitation or complete loss of contractility of the involved muscles. Usually the first muscles to be affected are those of the extremities, most often the lower. The condition then gradually spreads to eventually involve nearly every muscle in the body. The muscles of the face and lips have apparently escaped in all cases that have been thus far described.

Considering the pathological changes present in the muscle tissue, one would expect pain to be a prominent and conspicuous symptom. On the contrary, it was entirely absent in the majority of the reported cases, and in those in which it was present, it occurred early in the disease and was a minor complaint of short duration. Janicke's² case had slight pain early in the course of the disease. In Hoover's⁸ case and that reported by Gies³ the muscles were said to be sensitive to pressure. Weakness and loss of weight were the outstanding constitutional symptoms. Fever was not mentioned as occurring in any of the cases.

The characteristic feel of the muscles on palpation is the outstanding

TABLE I
A Brief Summary of the Clinical Findings in the Reported Cases of Generalized
Myositis Fibrosa

Case No.	Sex	Race	Presenting Symptom	Flap	Pain	Extent of Involvement	Duration	Skin Lesions	Outcome	Remarks
1	F	W	Swelling of the sternomastoid muscle and stiffness of the neck	None	Yes, early Not severe	Generalized, most marked in the neck, shoulder girdle, and arms	1 month	None	Improved some under treatment Progressive, not followed	Under observation 4 months
2	M	W	Stiffness of the arms and legs	None	None	Generalized, began in legs and abdomen	5 years	None	Death	Marked contractures
3	F	W	Drawing up of the leg	None	None in the muscles, the shoulder	Generalized except muscles of face Considerable atrophy	2 years	Skin of hands involved later	Living at present	Pyelitis and frequent sore throats Worse during pregnancy
4	F	W		None	Muscles were sensitive to pressure	Generalized with marked atrophy	2 years	None	Death	Not proven microscopically
5	M	W	Pain in the rt leg, later painful swelling of the thigh	None	Pain on palpation	Muscles of rt thigh, later the calf muscles of same leg	Several months	Overlying skin like leather, adherent to muscles	Improved under treatment	Carbuncle a year before onset of illness
6	F	W	Fatigue, pain in the back, and stiffness of the legs	None	Early but none later in the course of disease	Practically every muscle in body Marked atrophy	1 year?	Rash over arms and hands early	Not followed	Not proven microscopically Loss of reflexes
7	M	W	Stiffness of the legs	None	None	Calf muscles of both legs	3 years	Skin over muscles hard and indurated	Improved under treatment Not followed	Arthritis of both knees during illness Similar attack before
8	M	B	Stiffness of the legs	None	None	Generalized except small muscles of face	1 year	None	Death	Pulmonary tuberculosis

diagnostic point. The muscles feel distinctly harder than normal and seem to be increased in consistency. To the palpating hand they impart the sensation of being edematous without any extension of the process to the subcutaneous tissues, they may be described as doughy or boggy. In the early stages of the disease the muscle volume is well preserved, in advanced stages there is a marked decrease in size and on palpation the muscles feel hard and boardlike. With the decrease in size of the muscles, resulting from contraction of scar tissue, there is an associated shortening which produces marked limitation of movement, a condition which eventually renders the patient completely helpless.

DIAGNOSIS

Although positive diagnosis is possible only after microscopic examination of the muscles, their characteristic feel on palpation, the impairment of their function, the absence of pain, the lack of constitutional symptoms, and the chronic progressive nature of the condition constitute a clinical picture which can be confused with few other diseases. The absence of skin lesions readily differentiates myositis fibrosa from the chronic form of dermatomyositis. The primary progressive myopathies or muscular dystrophies offer little difficulty in the differential diagnosis. The familial manifestations, the tendency to a symmetrical involvement of muscle groups, and the marked atrophic, or in some instances the pseudohypertrophic, changes in the muscles are the outstanding points to be remembered. In the myopathies weakness of the involved muscles is

the outstanding symptom, whereas in generalized myositis fibrosa stiffness of the muscles is the predominant functional derangement.

CREATINE METABOLISM

A detailed study of the creatine metabolism having been reported in an earlier publication,¹³ only a brief summary of the essential findings will be attempted in this connection. Derangement of the creatine-creatinine metabolism, particularly as regards the abnormal excretion of creatine in the urine, is a well-known manifestation of muscle disease. In the present case the creatinuria was particularly marked, more than 40 per cent of the so-called "total creatine"* being excreted as creatine, even on a meat-free diet. For the critical evaluation of this result two complicating factors should be borne in mind, the age of the patient and the co-existence of tuberculosis. As to the influence of age, there is inadequate information concerning the creatine metabolism in early adolescence, but such data as are available indicate that at the age of 14 and 15, creatinuria is either absent or of relatively small quantitative importance. Of perhaps greater significance is the influence of pulmonary tuberculosis. On the one hand, there are the careful observations of McClure¹⁴ which demonstrate that creatinuria is not characteristic of this disease and on the other hand there is the work of Thompson¹⁵ which emphasizes that creatinuria is associated with pulmonary tuberculosis. It is probable

*This refers to the total creatine, creatine and creatinine, expressed as a percentage of creatinine.

judicious, therefore, to admit, for the present, the possibility that the age of the patient and the co-existing tuberculosis were contributory factors, but at the same time, it is quite obvious that the high grade of creatinuria was due primarily to the disease of the muscular system

Since the creatine-creatinine metabolism reflects the endogenous metabolism, moderate variations in protein intake exert little, if any, effect in the normal individual, the creatinine excretion being maintained at a practically constant level. In contrast to this is the pronounced effect which the addition of meat to the diet produced in the case under consideration. With an increase in protein metabolism of approximately 70 per cent (from 10 gm of urinary nitrogen in 24 hours to 17.07 gm), the "total creatinine" was raised from 1.28 gm to 2.25 gm, an increase of 1.27 gm, of which 0.99 gm (78 per cent) was in the form of extra creatine.

Normal human voluntary muscle contains approximately 400 to 500 mg of creatine per 100 gm. Apparently it is capable of storing creatine above this level, as shown experimentally by Chanutin¹⁶ and as is evidenced by the fact that if creatine is fed a considerable portion is retained. The storage of creatine proceeds until a point is reached when more and more of the ingested creatine is excreted in the urine. Presumably a level of saturation exists and after it is attained practically all of the ingested creatine, even in the normal individual, is promptly eliminated in the urine. It has been observed by one of us (M. B.) in unpublished experiments on

himself, that when 10 gm of creatine hydrate are ingested daily, the amount of creatine eliminated, though small at first, increases daily, but just as soon as the feedings are discontinued, creatinuria promptly disappears. The creatinine level of excretion, however, remains elevated for a considerable after-period, the extra creatinine owing its origin to the metabolism of a part of the extra creatine stored in the muscle (see also Benedict,¹⁷ Rose *et al*¹⁸). It is well known that this capacity for the storage of creatine is diminished in various muscle diseases, and therefore it was not surprising to find that this was true also in myositis fibrosa. Nevertheless, it was remarkable that there was almost complete inability to store the creatine for more than very short periods. On the administration of 1 gm of creatine hydrate (equivalent to 0.758 gm of creatine, in terms of creatinine), all was recovered within 24 hours, 92.1 per cent as creatine and the remainder as creatinine. On feeding 2 gm of creatine hydrate, 91 per cent was recovered within 48 hours, and in a subsequent experiment, 96.5 per cent. When 5 gm were fed, 91.73 per cent was recovered within 3 days. The obvious explanation is that the muscles possessed low saturation levels, so low in fact that even the creatine arising from the endogenous metabolism could not be retained sufficiently long to permit its normal metabolism to creatinine.

Analysis of various muscles, most of which were obtained soon after death, showed that their creatine content was abnormally low in all instances and as has been stated else-

where,¹³ a definite relationship was demonstrable between the creatine content and the degree of inflammation. Thus, the soleus which showed least inflammation contained the largest amount of creatine (324 mg per 100 gm), whereas the iliacus which showed the greatest degree of inflammation, contained, next to the diaphragm and myocardium, the least amount of creatine (160 mg). It is worth noting that the diaphragm and heart muscle likewise showed definite pathological changes (degeneration, inflammation, fibrosis). The former contained 159 mg of creatine per 100 gm of tissue, as compared with normal values of 357 to 364 mg obtained by one of us¹⁹ with the same method of analysis (Ochoa and Valdecasas²⁰). The myocardium also contained 159 mg of creatine per 100 gm. Analysis of heart muscle in two cases of sudden accidental death yielded values of 265 and 285 mg, respectively.

The inescapable conclusion is that in myositis fibrosa a definite relation exists between the degree of inflammation and the amount of creatine which the muscle contains and which it is capable of storing. For purposes of comparison, the composition of dis-

eased and normal muscle is summarized in Table II.

These results have a double significance. In the first place it is quite obvious that the creatine content of muscle in myositis fibrosa is much lower than normal, in the second place these closely approach the saturation level, whereas the data given for normal muscle are perhaps 10 to 30 per cent below the saturation level.

The uric acid content of the blood was relatively high, averaging 5.5 mg per 100 cc in a series of six analyses of the blood taken at different times during the course of the disease. In part this may be attributed to the co-existing tuberculosis and in part to the somewhat exaggerated nuclear metabolism accompanying the destructive changes in the muscle.

From the standpoint of diagnosis, the marked creatinuria and the extremely low tolerance for exogenous creatine are considered to be valuable criteria, as is also the low creatine content of the muscle.

PROGNOSIS AND TREATMENT

A consideration of the small number of reported cases justifies the conclusion that the outlook is not hopeful.

TABLE II
The Creatine Content of Muscle Normally and in Myositis Fibrosa
Muscle creatine in mg per 100 gm of fresh tissue*

MUSCLE	NUMBER OF SUBJECTS	NORMAL	MYOSITIS FIBROSA
Diaphragm	(3)	357-364-364	159
Myocardium	(2)	268-285	159
Deltoid	(2)	421-470	197
Sartorius	(1)	442	222
Intercostals	(2)	442-368	172
Psoas	(3)	470-483-470	222
Soleus	(1)	422	324

*Analysis by the method of Ochoa and Valdecasas.

The disease is progressive in nature. Its duration is variable. Batten's⁷ case lived 5 years. The one reported by Burton, Cowan, and Miller^{6,21} is living at the present time. Hoover's⁸ case lived only two years. In the remainder of the cases the duration of life was not mentioned. In the later stages of the disease the patient's general health undergoes marked deterioration and death from some intercurrent infection is probable.

Little can be said as regards therapy. Drugs are of no value. Massage has been very beneficial in one of the reported cases.⁶ Careful search for foci of infection should be made and when found such should be eradicated if possible as this measure might have some influence on the course of the disease. Massage, gymnastic exercises, and electrotherapy theoretically should be beneficial.

Roentgenologic Diagnosis of Early Pulmonary Tuberculosis

By B R KIRKLIN, M D, F A C P,
Rochester, Minnesota

THE value of roentgen rays in the early diagnosis of pulmonary tuberculosis has been a theme of controversy in the past, on the assumption that it was a rival of the clinical examination. At present it is commonly granted without question that the two methods are complementary, mutually helpful, mutually corrective, and almost indispensable to each other. Accordingly, the practitioner of either may point out its advantages without seeming to boast, or admit its limitations without seeming to make reluctant concession.

With respect to the technic of roentgenologic examination of the lungs, it will be sufficient to say that roentgenoscopic study is inadequate either to disclose or exclude the presence of small tuberculous lesions, and that roentgenography, which preferably should be stereoscopic and rapid, is essential for decisive results. At The Mayo Clinic it has been found advantageous to make the roentgenograms at

a distance of six feet, with high milliamperage and an exposure time of only a fraction of a second. By this means the blurring and obliterating effect of voluntary, respiratory or cardiac movement is precluded.

Obviously roentgen rays cannot reveal evidences of tuberculosis until demonstrable differences of density of the tissues have been produced by the infection. Rarely, cases with clinical manifestations suggestive of the disease give no roentgenologic signs. But the converse occurs far more often, and very many cases can be cited in which the affection was disclosed by roentgen examination when clinical symptoms and signs were vague and trivial, or absent altogether. Sampson and Brown¹ have said that in a surprisingly large number of cases definite changes characteristic of tuberculosis are seen in the film long before definitely abnormal physical signs can be detected. They have stated, further, that among 1367 consecutive cases at Trudeau Sanatorium, the physical signs in 32 per cent were either absent or so slight that the diagnosis was established entirely, or in large part, from study of the films. Webb² has said, succinctly, that roentgenologic examination is the chief method

od available for detecting early pulmonary tuberculosis

EARLY TUBERCULOSIS OF ADULTS

Almost all cases of incipient tuberculosis of adults may be divided into two groups. In the first group, which comprises by far the greater number, the earliest significant manifestation is a relatively faint shadow in an upper lobe, more often that of the right lung (figures 1*a* and *b*). As seen stereoscopically, the dense region is more or less conical, on the single film it appears to be fan-shaped. Its base is at the periphery of the lung, and is often directed toward the axilla, its apex points toward the hilum. It lies obliquely below the clavicle, usually in the first interspace, occasionally in the second, and its long axis corresponds to an external twig of the ascending branch of the main bronchus. On close

inspection, the shadow is seen to be made up of a confused network of delicate lines enveloped in a filmy veil. Its appearance has been likened aptly to that of a web spun by caterpillars about an outer branch of a tree.

In the second group, the lesions are likewise situated in the outer parenchymatous portion of the subclavicular region but are more or less spherical in form (figure 2*a*). More often they are multiple, but they may be single. When multiple they are grouped, but in such variable degrees of proximity to each other that they may plainly be discrete or apparently confluent. Their size varies from a diameter of 1 or 2 mm to several centimeters, and multiple foci are likely to be diverse in size. Their shadows are faint, although denser at the center than at the periphery, the latter being especially hazy and indistinct.

1. *a*, faint shadow in the upper lobe of the right lung, *b*, close-up of roentgenogram of shadow in *a*, *c*, multiple shadows in the upper lobe of the right lung.

Common to both groups is an accentuation of the bronchovascular trunk leading from the affected region to the hilum. Occasionally the ribs on the affected side descend more steeply, and the intercostal spaces are narrowed, although these phenomena more often accompany advanced than early disease. Not infrequently the unaffected lung appears to be more brilliantly transradiant than normally. Roentgenoscopically, respiratory excursion of the diaphragm on the diseased side is likely to be restricted, and the apex is often less bright than its fellow. But restriction of diaphragmatic movement occurs in many diseases other than tuberculosis, and apical darkening not only has other pathologic causes but is often devoid of significance. Lesions in the apical field above the clavicle are rarely en-

countered early in tuberculosis, when they are present the disease almost invariably is well advanced and then its manifestations below the clavicle are more conspicuous.

In the differential diagnosis four prime characteristics of early tuberculosis are to be kept in mind: namely, its situation below the clavicle and in the outer parenchyma of an upper lobe, the roughly conical or spherical form of the lesions, the softness and lack of marginal definition of the shadows, and the accentuation of the tributary bronchovascular stem. Few of the simulants have all these characteristics. Among such simulants to be considered are bronchiectasis, malignant metastasis, the lateral border of an azygos lobe, shadows from extraneous causes, accentuation of bronchovascular markings without correspond-

FIG. 2a. Nodular type of lesions in right upper lobe, shadow in center of image representing the outer border of an azygos lobe.

ing parenchymal shadows, localized simple pneumonitis, and small, healed, tuberculous lesions

Bronchiectasis in an upper lobe is usually depicted as a mottled, irregularly triangular shadow with its apex toward the hilum. However, bronchiectasis seldom affects upper bronchi, even in this event the lesion is essentially bronchial, and, although the corresponding parenchymal alveoli may be atelectatic, the more striking shadows are central rather than peripheral.

A malignant metastatic nodule in the infraclavicular region may imitate an early conglomerate tubercle. But metastatic nodules are most often numerous when discovered, and are likely to be widely scattered in several lobes. Further, a metastatic nodule is likely to be more regularly spherical, denser, and more sharply defined than a tuberculous nodule. An azygos lobe in the superior mesial portion of the right lung is not altogether rare (figure 2b). Its lateral border is represented by a curving shadow resembling an inverted and elongated comma. Since an azygos lobe is somewhat unusual, this shadow may be mistaken for an indication of disease, and its situation may suggest the thought of tuberculosis, but other essential features of tuberculosis are lacking. During the process of roentgenography, certain patients, especially women, are sometimes permitted to wear a cape, or other light clothing which may produce a faint shadow over the apical region. On inspection, however, the cause of the shadow should be apparent, but it is not infrequently the patient's chest is not properly exposed.

adults habitually arises from recrudescence of the primary infection acquired in childhood by retrograde extension from the hilar nodes into the lymphatic channels, especially the upper trunks, and thence into the parenchyma of the lung, has been responsible for many wrong diagnoses. This hypothesis was popularized by certain continental roentgenologists, and until a few years ago was widely accepted. Intensification of the hilar shadow and of the principal vascular markings, together with a so-called beaded or varicose appearance of the trunks, was deemed sufficient warrant for the diagnosis of "peribronchial tuberculosis." In the course of time, however, it was learned that frank tuberculosis almost never developed in cases in which such manifestations occurred, and that these appearances are often found in persons in robust health. Then the phrase, "peribronchial thickening" came into frequent use, but this expression is equivocal and so susceptible of erroneous interpretation that it is falling into disfavor. At all events, few roentgenologists will take responsibility for even a tentative diagnosis of tuberculosis unless the abnormal shadows extend to the peripheral portion of the lung, where shadows of the vessels are not normally visible.

Restricted, simple pneumonitis in an upper lobe, resulting from a cold or other ordinary infection, is a highly deceptive simulant of early tuberculosis. The morbid change may appear as a faintly shadowed conical segment, probably representing congestion chiefly, or as a small mottled patch depicting narrowly localized bronchopneumonia. In either instance the situation

and general character of the shadow, together with the intensification of the corresponding vascular marking, are identical with those of one or the other type of early tuberculous lesion, and the roentgenologist will be inclined consistently to make the latter diagnosis, at least provisionally. It is in such cases that the clinician can avert a wrong diagnosis by temporarily withholding final judgment, observing the course of the disease, and sending the patient for reexamination later. Fortunately, the acute, simple, pulmonary infections usually attack lower lobes, and invasion restricted to an upper lobe is rare, but it should be kept in mind when colds, pneumonia or influenza are prevalent.

ACTIVITY

Inability of the roentgenologist to distinguish with precision between ar-

rested and active lesions is an important source of error. The majority of healed lesions are dense and sharply delimited from the normal tissue (figure 3a), they are likely to be accompanied by calcified lymph nodes at the hilum or elsewhere, often the interlobar pleura, especially that of the right upper interlobar fissure, is visibly thickened. Conversely, most of the early active lesions cast thin shadows which merge indefinitely with those of the normal tissue, and they are seldom associated with calcified nodes or interlobar thickening (figures 1, a and b and 2a). But between the cases which are manifestly active and those which are plainly inactive, are many in which the degree of density and of marginal definition is hard to evaluate, and decision depends too largely on the personal equation of the examiner. Sometimes,

FIG 3a. Healed tuberculous lesions in the upper lobes. In the seventh interspace, posteriorly on left lung. Calcified lymph nodes may be noted.

also, the roentgenologic indexes of activity or inactivity are not reliable; an apparent perifocal haziness may be the result of movement; lesions remote from the film appear less dense and less clearly defined than they would if near the film, density and marginal definition vary with the quality of the rays. For these reasons the roentgenologic opinion should always be subject to clinical review. As a single test of activity the roentgenologic examination is probably equal to any other; but no single test is a sufficient basis for such a momentous decision.

In very rare instances tuberculosis of adults is limited to a lower lobe or to the circumhilar region, and its manifestations are identical with those often observed in children. Although the pathologic changes are obvious at an early stage, the roentgenologist cannot logically attribute them to tuberculosis. In fact, when abnormal shadows are found only in a middle or lower lobe, the presumption is strong that they are not due to tuberculosis but to some other disease. As a rule, the appearance is suggestive of restricted, simple bronchopneumonia, and is so interpreted. The symptoms and physical signs are also so contradictory or confusing that usually the proper diagnosis is made only after a period of observation.

TUBERCULOSIS OF CHILDREN

Early tuberculosis of children has many points of difference from that of adults. It is commonly accepted that, before puberty is reached, virtually all children within the precincts of a tuberculosis have been infected with the bacillus of tuberculosis, and Ghon's

theory that the initial pulmonary lesion arises in the parenchyma is generally endorsed. But wherever the portal of entry may have been, the intrathoracic lymph nodes are by far the most common manifest site of reaction to this infection. Subsequently any of several results may follow: (1) healing or arrest, as occurs in the great majority of cases, (2) development of clinically important, primary, focal tuberculosis directly or indirectly from the parenchymatous or nodal focus, (3) development of miliary tuberculosis, and (4) development of an adult type of tuberculosis from new, secondary infection after subsidence of the primary infection.

Since primary tuberculous infection in children is the rule, roentgenologic confirmation of the fact, even if feasible, would be superfluous. A few roentgenologists have interested themselves in the Ghon focus. This is commonly small, situated in any lobe, whether upper or lower, and revealed as a variously shaped shadow in the parenchyma, but only after the lesion has passed its earlier stages (figure 3, *b*). Such a shadow is likely to be found in the roentgenogram of any child's chest, but identification of the shadow as that of a Ghon focus is necessarily uncertain. A roentgenologic diagnosis of tuberculous mediastinal lymphadenopathy is also insecure. In roentgenograms of children who have no clinical evidence of disease, the mediastinal shadow is usually wide, the lymph nodes about the hilum on both sides are frequently depicted, and the larger vascular markings seem to be accentuated. If the subject were an adult the picture would be abnormal, but since it is usual in

childhood it must be rated as normal. Often, especially in younger children, the adenopathy is more pronounced; the mediastinal shadow is vastly widened bilaterally, and its borders may be straight, convex, or polycyclic. However, identical manifestations may follow various infections of childhood, especially measles or whooping cough, and may persist for many weeks. In any case, therefore, the cause of the adenopathy is a problem to be solved by the clinician rather than the roentgenologist. Even when the primary infection in children has given rise to early parenchymal disease of actual or potential moment, difficulties in its roentgenologic recognition persist. The lesion may appear in any of the lobes, but it has a predilection for the circumhilar region or for the lower portion of the lobe invaded. Its shadow is of sufficient size and density to be obvious and may be somewhat fan-shaped, or irregular, or, if at the hilum, irregularly hemispherical. Wherever it may be, it inclines to a central, rather than a definitely peripheral situation. The mediastinal shadow is widened, perhaps lobulated, and the radicular markings are emphasized. On the whole, the picture is rather plainly that of localized pneumonitis, but whether simple or tuberculous can scarcely be determined positively from the roentgenologic appearance alone. If the examiner attempts to carry his interpretation farther he will be likely to consider bronchopneumonia, tuberculosis, and lobar pneumonia, the order of choice varying according to his most impressive experience and the more striking features of the case at hand. Always, if he is duly cautious, he will

make his diagnosis conditional on clinical confirmation and will suggest the various alternatives. The clinician also is often hampered by the indefinite or eccentric physical signs and the difficulty of obtaining satisfactory sputum tests so that extended observation may be required for final decision.

MILIARY TUBERCULOSIS

Inasmuch as diffuse hematogenous miliary tuberculosis often arises from a small hidden pulmonary or nodal focus or from one which is remote and unsuspected, it is perhaps entitled in such circumstances, to inclusion among early forms of the disease. In the absence of definite knowledge of an antecedent focus an independent clinical diagnosis is almost impossible, whereas roentgen rays usually will reveal the condition and often identify it positively. During the earliest stages of pulmonary invasion roentgen rays may fail to disclose any evidence of the disease, and death may occur, especially of infants before any changes can be demonstrated on the film. Notwithstanding such exceptions, roentgen rays in the majority of cases give a definite picture and one which is perhaps the most characteristic of any variety of tuberculosis. At first, mere veiling of the pulmonary markings may be seen, but shortly the tubercles also are visible as a multitude of minute flecks distributed more or less evenly over all parts of both lungs. The resulting pulmonary shadow has been described variously as having a granular mottled marbled or stippled appearance. To me it seems to resemble a sponge the texture of which

varies from exceedingly fine to moderately coarse (figure 4)

Despite the almost pathognomonic evidence afforded by roentgen examination, dependence on it should not be absolute. Of diseases which may enter into the roentgenologic differential diagnosis the most common are malignant miliary metastasis and pneumoconiosis, particularly that produced by organic dust. Their chief marks of distinction are the following. Miliary metastatic lesions, although small, are very diverse in size, commonly denser than miliary tubercles, and most nu-

merous in the lower two-thirds of the lung. Pneumoconiosis ordinarily spares the apexes and is most manifest about the hilum; the individual lesions are likely to be larger, more irregular in size and shape, and denser than miliary tubercles. Accordingly, the examiner usually can venture a specific diagnosis, but prudence demands that it have clinical approval.

COMMENT

I am aware that this appraisal of the capabilities of the roentgen rays in the diagnosis of early pulmonary tubercu-

Fig. 4. Miliary tuberculosis. The left image is a frontal view and the right is a lateral view. Both illustrate the appearance of miliary tubercles.

losis may seem unduly conservative to many who have implicit confidence in the roentgenologic examination, or may appear unduly liberal to the smaller number who are skeptical of the method. To the skeptics it may be pointed out again that without employment of roentgen rays as a routine, most of the truly early cases will escape recognition. Indeed, as a single rapid method for the definite revelation of the lesion, the determination of its probable nature, and even the estimation of its activity, I do believe that the roentgenologic examination is not surpassed by any other. Nevertheless, I have dwelt on its limitations because there is a prevalent tendency toward unquestioning reliance on laboratory tests. Although this flattering faith has been a

stimulus to roentgenologic progress, it has sometimes led the roentgenologist into incautious or unqualified interpretations. It has been difficult to learn that the normal chest has a wide range of variations, and that not all adventitious shadows are significant of present disease. Consequently the novice, and sometimes even the expert, are inclined to the diagnosis of tuberculosis when none exists. Many sound or nontuberculous persons have been sent to sanitariums on the basis of a roentgenologic opinion which the clinician failed to verify. In short, while the roentgen rays have brilliantly illuminated the field, the clinician still is obliged to study all the landmarks critically before he assents to a diagnosis so grave as that of tuberculosis.

III. MEDICAL HUMORISTS

SAAVEDRA Miguel de Cervantes (1547-1616) the greatest of Spanish writers, bent upon the alleviation of all the ills of mankind, was a doctor in very truth. He early commenced writing verses, and his pastoral, "Fílana", attracted the attention of Cardinal Acquaviva whom he accompanied to Italy as page. In 1570 when serving in the war against the Turks and African corsairs, he lost the use of his left hand. In 1583 he retired from service and recommenced his literary work, publishing in 1584 his pastoral "Galatea". He lived by writing for the stage, to which he contributed between twenty and thirty plays only two of which have

Received for publication, November 28, 1951

Send to Editor: Previous items in this series were in Medical Men as Musicians, Vol. 1, No. 160, in 1937-1934, and History of Music, Vol. 1, No. 160, in 1930, in 1937-1934. Dr. Weidell had planned a series of articles on the contemporary music scene, but the war had the effect of putting it off. He had to wait until the war was over at the time of the 1945-1946 season. He had to wait until the war was over at the time of the 1945-1946 season. He had to wait until the war was over at the time of the 1945-1946 season.

survived In 1605 he produced the first part of Don Quixote and it had a hearty reception from the beginning among the populace, though not among the cultured classes Between 1613 and his death were published his twelve "Exemplary Tales", "Journey to Parnassus" and eight new dramas The second part of "Don Quixote" was also completed during these years and it is the masterpiece through which his fame lives

Francois Rabelais (1490-1553) was at first a monk, but having been punished for some indecorous behavior, he quitted the Benedictine order, studied medicine at Montpellier, and later practiced as a physician. In 1532 he went to Lyons as hospital physician. In 1536 Rabelais obtained from the pope absolution for the violation of his monastic vows and permission to practice medicine and to hold benefices. During most of 1546 and part of 1547 he was physician to the town of Metz. Rabelais was the author of several books but the only one by which he is known is the romance called, "The Lives, Heroic Deeds, and Sayings of Gargantua and Pantegrue", an extravaganza satire upon monks, priests, popes and pedants, in which much obscene

and absurdity are blended with learning, wit and humor Rabelais made one of the first Latin translations of the aphorisms of Hippocrates (Lyons, 1532) He was the first to lecture on medicine at Montpellier with the Greek text before him

Tobias Smollet (1721-1771) was educated in Dumbarton and at Glasgow Universities where he studied medicine After some years of apprenticeship with a surgeon, a Dr John Gordon, he went to London His interest, however, was rather in literature than in surgery and in 1739 made an attempt, but was unsuccessful in having his tragedy "The Regicide" performed After some years' service as surgeon's mate on board the Cumberland, he returned to England and again took up literature The first of his picaresque novels, "Roderick Random", appeared in 1748, and its success was immediate and great His second novel, "The Adventures of Peregrine Pickle" (1751), was even more successful He practiced as a physician at Bath, and in 1753 returned to London, gave himself up to literature and wrote "Ferdinand Count Fathoms" He made a lively but inaccurate version of "Don Quixote" (1755), published a "History of England" in four volumes (1757), and "Sir Lancelot Greaves" (1760), a weak imitation of "Don Quixote" After a tour of Italy Smollet published his "Travels" In 1769 he produced his coarse satire "The History and Adventure of an Atom", dealing with politics in England during the previous fifteen years In 1771 he wrote his masterpiece, "The Expedition of Humphrey Clinker"

Oliver Goldsmith* (1728 - 1774) went to Edinburgh to study medicine Here he remained eighteen months, during which time he acquired some slight knowledge of chemistry and natural history At the end of this period he went to Leyden, where he studied for nearly a year, and afterward he wandered over a large part of France, Germany, Switzerland and Italy He had no money to pay his expenses during his walking tour, but his kindness and humor won him friends everywhere, and his skillful playing of the flute gained him a scanty living While at Padua he took a medical degree He returned to England in 1756 where he commenced practice as a physician, in which he was unsuccessful He then entered the field of letters and his first work to attract attention was an "Inquiry into the Present State of Polite Learning in Europe" (1759) To this succeeded, "The Citizen of the World" a "Life of Beau Nash" and a "History of England" Becoming acquainted with Dr Johnson in 1761, the latter introduced Goldsmith to the Literary Club In 1764 appeared "The Traveler" which at once placed Goldsmith in the front rank of English authors Two years afterward appeared the "Vicar of Wakefield" Following in rapid succession came "The Good-Natured Man" (1767) "History of Rome" (1768) and the exquisite poem "The Deserted Village" (1770) In 1773, his immortal comedy of "She Stoops to Conquer or Mistaken for a Night" took the public by storm His

*See also *Recesses*, L. H. Oliver Goldsmith, M.D., and his *Medical*, p. 12. [L. H. Oliver]

other works are "Grecian History" (1774), "Retaliation" a serio-comic poem (1774), and "History of Animated Nature" which he did not live to finish. Washington Irving has written a remarkably sympathetic biography of Goldsmith.

Charles Jones Lever (1806-72) graduated in arts at Trinity College, Dublin, in 1827, and in medicine in 1831, taking his doctor's degree a little later at Gottingen. He then returned to Ireland to practice. In 1834, he contributed his first paper to the newly-started "Dublin University Magazine" of which he became editor in 1842. The first chapter of "Harry Lorrequer" appeared in that magazine in 1837. Meanwhile he was attached as physician to the British legation at Brussels, where he practiced for three years. During his three years editorship of the "Dublin University Magazine" he resided near Dublin, and afterwards lived on the Continent, devoting himself to fiction writing. "Charles O'Malley", "Tom Burke", and "Jack Hinton" are representative novels and in a class by themselves. He also wrote "Arthur O'Leary" and "Roland Cashel".

Oliver Wendell Holmes (1809-94) graduated from Harvard in 1829, in the class which he himself made famous in later years by his yearly poems at its reunions. After studying law for a time, he turned to medicine, at first with little seriousness. He became deeply interested, however, and during which he studied medicine he was most industrious. His first degree of M.D. was conferred in 1832, and he settled down to practice in Boston. While

yet in college, Holmes wrote numerous poems including "The Spectre Pig" and "The Height of the Ridiculous". Following his graduation from Harvard he wrote "Old Ironsides". In 1839 he was given a position as lecturer on anatomy and physiology in Dartmouth College and in 1847 gave up his practice entirely and became professor of anatomy at the Harvard Medical School, a position he filled until 1882. Various medical papers, some of which were of great importance in the profession, such as "On the Contagiousness of Puerperal Fever" (1843) and "Puerperal Fever as a Private Pestilence" (1855) came from Holmes' pen from time to time, and his poems written to celebrate every special occasion in his beloved city of Boston made him locally famous as a wit. It was not until the founding of the "Atlantic Monthly" in 1857, however, that Holmes became widely famous. He contributed his papers "The Autocrat of the Breakfast Table" which are up to the present day considered his masterpiece. His first series was followed by "The Professor at the Breakfast Table" and later by "The Poet at the Breakfast Table". He wrote three novels, "Elsie Venner, A Romance of Destiny", "The Guardian Angel" and "A Mortal Antipathy". After a visit to Europe in 1886 appeared "Our Hundred Days in Europe" and when Holmes was eighty, he wrote a final autocrat series under the title of "Over the Teacups". Among Holmes' best poems may be mentioned "The Chambered Nautilus", "The Last Leaf", and the "The Wounded Hussar".

IV MEDICAL MEN AS INVENTORS

Joseph Ignace Guillotine (1738-1814) went to Paris, where he practiced medicine with such success as to win recognition as one of the foremost physicians of the day. When the Revolution broke out, he became one of its ardent supporters and suggested that a decapitating machine be used in inflicting the death penalty. After the rise of Napoleon he resumed his practice in Paris where he was one of the earliest and most earnest champions of vaccination.

Richard Jordan Gatling (1818-1903) graduated from the Ohio Medical College in 1850. He assisted his father in perfecting a machine for sowing cotton seed and another for thinning out cotton plants. In 1850 he invented a double acting hemp brake and in 1857 a steam plow. His principal invention and the one by which he became famous was the revolving machine gun which bears his name (1861). In 1886 he invented a new gun metal of steel and aluminum.

Rufus Henry Gilbert (1832-85), after graduating at the College of Physicians and Surgeons in New York City, began medical practice at Corning, N. Y. At the outbreak of the Civil War he became a surgeon in the Duryea Zouaves (Fifth New York Infantry) and rose to be medical director and superintendent of the Central Railroad of New Jersey. Gilbert was appointed superintendent and medical director of the United States army hospitals. Owing to the failure of his health during the war he abandoned his profession and engaged in the railroad business making a special study of the needs of rapid transit in New

York. The result was the erection (1878) of the Sixth Avenue Elevated Railway in that city.

Alexander Graham Bell (1847-1922) received his medical education at the University College, London, and the London University. In Elgin he was for two years resident master and teacher of elocution and music. He was greatly interested in his father's system of instruction of the deaf and dumb and in 1872 he became professor of vocal physiology in Boston University. Among his most important inventions are the harmonic multiple telegraph (1874), the fundamental method that underlies the electric transmission of speech to any part of the world (1895), the magneto-electric speaking telephone (1875), the photophone for transmitting speech and other sounds to a distance by means of a beam of light (1880), an induction-balance with magneto-electric telephone for painlessly locating bullets or other metallic masses lodged in the human body (1881), the telephone probe to determine the position of bullets or other metallic masses lodged in the human body (1881), the spectrophone for determining the range of audibility of different substances in the spectrum (1881), joint invention of the graphophone, tetrahedral kites (1903), joint invention of a number of improvements designed to promote aerial locomotion.

Carl Auer von Welsbach (1858-) attended the University of Vienna and at Heidelberg (1880-82). In 1885 he discovered two new elements "thorium" and "neodymium" and invented the incandescent gas lamp known by his name. He received the

osmium incandescent electric lamp in 1898, and in 1907 discovered another new element known as "lutecium"

V MEDICAL MEN AS EXPLORERS

David Livingstone (1813-73) was a graduate of the Faculty of Physicians and Surgeons of Glasgow. Under the auspices of the London Missionary Society he went in 1840 as medical missionary to South Africa. He discovered the Victoria Falls of the Zambesi in 1855. From 1858 until his death, he prosecuted his labors as explorer and missionary in Africa.

Elisha Kent Kane (1820-57) obtained the degree of M.D. at the University of Pennsylvania in 1842. He was attached as surgeon to the American mission to China and afterwards visited India, Egypt, and Greece. In 1850 Kane joined the Ginnell Expedition, as medical and scientific member, in the unsuccessful search for Sir John Franklin. His fame as an Arctic explorer rests on his second expedition, in search of Franklin in 1853-55. He sailed from New York in the brig "Advance" and reached lat 78°

41' N, the point farthest north attained up to that time by a sailing vessel.

Hays, who accompanied Kane, was also a physician.

Sir Wilfred Thomason Grenfell (1865-) graduated in medicine at London Hospital. In 1889, under the auspices of the Royal National Mission to Deep Sea Fishermen, he equipped a hospital ship to accompany the fishing fleets from the North Sea ports to Iceland. Three years later he went to Labrador and Newfoundland, where he established hospitals at many points along the coast. He wrote many books, chief of which are "Off the Rocks" (1906), "Down to the Sea" (1910), "Down North on the Labrador" (1911), "The Adventures of Life" (1912).

Jean Baptiste Etienne Auguste Charcot (1867-) was educated in Paris and after graduating in medicine, was attached to several important hospitals. In 1903 he began a series of antarctic explorations in the region of the South Pole. His published writings are "France at the South Pole" and "Around the South Pole".

Editorial

THE COMPARATIVE COST OF MEDICAL JOURNALS

Faced with yearly deficits in the portion of its budget devoted to the purchase of medical periodicals, the Library of the College of Physicians and Surgeons of Columbia University undertook an analytical study¹ of the costs of the various medical journals purchased. It was soon found that the deficits were due in large measure to the impossibility of accurately determining the cost of certain periodicals in advance. While no such difficulty was encountered with the allowances for American, British or French journals, the estimates for German periodicals were frequently inaccurate. Many German medical publications are priced by the volume or by the part as issued, and in these days when there is such an urge to publish, the temptation to multiply volumes is very great. It is unfortunate that the German publishers do not adopt the fixed annual subscription plan. This would make it possible to regulate production and curb extravagant charges. Not only are several volumes crowded into one year but supplementary volumes, *Festschriften*, *Beihefte*, *Abhandlungen*, etc., are added, all at further increase in cost. The rank and file of American

medical readers must look to our libraries for these journals, and the libraries are naturally very desirous that their files should be kept intact. Present prices, however, are forcing cancellation in many instances, and with cancellations, other things being equal, prices must rise still higher for the cost of production is distributed over a smaller number of purchasers. During the year 1930-1931 the cost of certain important German medical periodicals was as follows: *Archiv f Dermatologie*, \$92.25, *Archiv f Psychiatrie*, \$103.57, *Deutsche Zeitschrift f Chirurgie*, \$62.88, *Strahlentherapie*, \$70.23, *Virchow's Archiv*, \$111.98, and *Zeitschrift f klinische Medizin*, \$74.55. If domestic subscription lists have fallen so low that foreign subscribers must be asked to pay such prices as those just quoted, it is high time that production costs were cut drastically. Material must be condensed and the number of pages and volumes reduced. Otherwise the present trend will prove to be suicidal. It would be a deplorable situation if the sequence of truly great journals with many decades of usefulness should be interrupted. Not all German medical periodicals fall into the price range quoted but the average annual cost of 88 of them received by the Library of the College of Physicians and Surgeons was \$36.11, while the average annual cost of 73 titles of American origin was \$7.91.

¹ROBERT, ALFRED L., and SCHATTENBERG, HANS H. The comparative cost of medical journals, *BULL. MED. LIBRARY ASSOC.*, 1932, 28: 140-155.

The cost per page affords a method for the private subscriber as well as for the library to arrive at comparative costs of periodicals. For a number of reasons this method is crude and inaccurate. Differences in size of page, quality of paper, number and type of illustrations and in the extent to which the subscription list is relieved of the necessity of carrying the full cost of production by endowments, subsidies, or income from advertising are factors—and there are many others—which enter into the cost per page. Since many of the operations in the production of a periodical are constant regardless of the number of copies issued, it follows that the cost per page can be lowered, either by reduction in the subscription price or by increase in the number of pages, as the list of subscribers grows. It is not surprising, therefore, that the Journal of the American Medical Association had a per page cost in 1930-1931 of but 0.16 cents. Returning to the national groups previously considered, the average cost per page of 88 German medical periodicals was found to be 1.88 cents while 73 American items had an

average cost per page of 0.58 cents. It is a source of satisfaction to find that the ANNALS OF INTERNAL MEDICINE was placed in the hands of its readers during that year at a cost of but 0.43 cents per page, well below the average of the American journals as a group. Even then it is not the lowest priced journal in its field, although it might be found to be such if the unit cost were weighted in respect to number and quality of illustrations used. The ANNALS will never be published for profit. In fact, it has required a subsidy from the general funds of the American College of Physicians in practically every year of its existence. With a growing subscription list, however, it should soon be not only self-sustaining but also in position to reduce the cost per page as well. That the price of subscriptions to our American journals is based on an annual volume assures the purchaser a fixed limit to his obligation and necessitates a fixed limit to the total output. It would be to the ultimate advantage of all medical libraries and of their patrons if the application of this system were made worldwide.

Abstracts

Dissection of the Aorta with Report of a Case. P. G. F. STONE, M.D. *Annals of Internal Medicine*, Vol. 15, No. 1, 1932, pp. 15-20.

The author has applied to both the human and the dog the method of dissection of the aorta which he has described in a previous paper. The results of the dissection of the aorta in the human and the dog are reported. The author has found that the aorta of the human and the dog is similar in structure and in the course of its course. The aorta of the human and the dog is similar in structure and in the course of its course. The aorta of the human and the dog is similar in structure and in the course of its course.

the three examples described in this paper, in the first, which occurred in a man 19 years of age, the occlusion was complete and death resulted from rupture of the aorta. The second was in a man, aged 38 years, in whom the lumen of the aorta was reduced to a diameter of about 2 mm, death being due to cardiac decompensation. The third patient was a child, aged 12 years. The diameter of the aorta at the point of rupture was about 10 mm. Death was due to

chronic nephritis and pneumonia. No one of these cases was diagnosed as to the coarctation during life. With the condition borne in mind, such findings as cardiac hypertrophy, widening of the aortic arch, evidences of arterial collateral circulation, retarded femoral pulse, and a systolic murmur over the major collateral trunks may make the diagnosis possible.

The Effect of Cabbage Feeding on the Morphology of the Thyroid of Rabbits. By ISOLDE T. ZECKWER, M.D. (Am Jr Path, 1932, viii, 235-244)

Feeding winter cabbage in the early part of 1931 to 17 rabbits for periods up to 114 days produced hyperplasia of the thyroid, but in only two instances were enlargements to more than twice the normal weight obtained. The microscopic changes were more conspicuous than the gross enlargement. The data obtained support the view of Webster, Marine and Cipra that there is an annual variation in the goiterogenic agent in cabbage, as well as seasonal differences and differences in the susceptibility of individual rabbits.

Cabbage and Goiter in Carpathian Ruthenia. A Contribution to Ethnic Pathology. By Prof. V. SUK, M.D., Ph.D. (Anthropologie, Prague, 1931, ix, 1-6)

Goiter occurs endemically in many parts of the Carpathian Highlands, and the worst goiter centers are found in those poor villages where, during the unfavorable months of the year, more than two thirds of the population live to a great extent on cabbage, with the addition of potatoes, corn bread and oats. How great a part cabbage, which is utilized as boiled *sauerkraut* plays in the dietary is indicated by the fact that a family of eight members may pickle as much as 1100 pounds for their own use. Examination of the children in this region

showed a much higher incidence of goiter in the villages using excessive amounts of cabbage. This difference was especially evident among girls. Whereas 26.5 per cent of all the girls examined were without goiter, only 7.9 per cent of the girls in three villages using excessive amounts of cabbage were free from thyroid enlargement. Of all the girls, 9.4 per cent showed marked thyroid enlargement. For the three villages using much cabbage, the comparable figure was 15.8 per cent.

Torula Infection. A Review and Report of Two Cases. By JAMES W. WATTS, M.D. (Am Jr Path, 1932, viii, 167-192)

Since Stoddard and Cutler pointed out the necessity of bearing torula infection in mind in patients with increased intracranial pressure without localizing signs, chronic meningitis, or other obscure cerebral conditions, the number of cases recognized has steadily increased. The first of the two here reported was in a woman, 32 years of age, in whom the infection was generalized although the symptoms were almost entirely cerebral. At autopsy a remarkable collection of pathological changes was found in the brain: diffuse meningitis, granulomas in the meninges, marked endarteritis and proliferation of adventitial elements of the meningeal vessels, an infarct in the pons, areas of softening in the cerebellum and various diffuse degenerative parenchymatous lesions. The second patient was a woman, 48 years of age, whose early complaints were headache, weakness and coldness of the extremities, inability to speak and difficulty in swallowing. At autopsy numerous cystic cavities from 1 to 8 mm in diameter were found in the brain. This case therefore corresponds to the embolic order of lesions as classified by Freeman. The respiratory tract is probably the portal of entry in most cases.

Reviews

A Text-book of X-Ray Therapeutics By ROBERT KNOX, completed and edited by WALTER M. LEVITT of the X-ray Department of St Bartholomew's Hospital, London, England. 250 pages, 106 illustrations. The Macmillan Company, New York City, 1932. Price, \$7.00.

At the time of his death Dr. Knox was engaged in the preparation of a comprehensive volume dealing with every branch of treatment by means of physical agents. However, only the sections concerning x-ray therapy were completed. These constitute an authoritative treatise on this subject as well as a memento of the work to which a great British radiologist devoted his energies for so many years. Dr. Levitt has very efficiently brought the text-book up to date, preserving the spirit of Dr. Knox's opinions on dosage and treatment, and keeping the balance between the claims of the more conservative therapists and the intensive methods of what might be called the newer school. Eight of the twenty chapters are entirely the work of Dr. Levitt. The subjects discussed are as follows: the effect of x-ray on tissues, the physics of x-ray therapy, x-ray measurements and dosage, the use of filters in x-ray therapy, with a description of the tubes and various types of high tension generators, the principles on which x-ray technique is based. About half of the text is devoted to these subjects, while the remainder is given over to a discussion of the various diseases in which the x-ray is used as a therapeutic measure. From the pathologist and the radiologist will be required a careful study of the anatomy of the various organs of the pre- and post-natal body. The representation of the human body in the text has been presented in a very clear and concise manner. The illustrations are of a high standard of quality and are well arranged. The text is well written and is easy to read. The book is a valuable addition to the library of the radiologist and the pathologist.

detail. The arrangement of the book is thoroughly logical, and the later chapters show a definite development from the physical and biological groundwork supplied in previous ones. The arrangement is excellent due to the careful outline and presentation of subject matter by organs and systems. A well chosen reference bibliography includes many classical articles which are of real value to the therapeutic radiologist. The book can be highly recommended as an excellent text for those who wish to learn some of the fundamental principles of x-ray therapy from a master. H. W. J.

Cytology and Cellular Pathology of the Nervous System. [By twenty-six contributors.] Edited by WILDER PENTFIELD, Professor of Neurology and Neurosurgery, McGill University, Montreal. In three volumes. xiv + 1267 pages; 886 illustrations (15 in color). Paul B. Hoeber, Inc., New York City, 1932. Price, three volumes, \$30.00.

This beautifully printed work, in three volumes of convenient size, is uniform in style with *Special Pathology*, edited by E. V. Cowdry, and with McClung's *Handbook of Microscopical Technique*. It is, in fact, a group of monographs by 26 internationally-known specialists in the fields of neurocytology and neuropathology. The first two volumes deal with the more fundamental considerations of normal and pathological cytology of the nervous system, while the third volume considers neoplasms, malformations and hematogenous reactions. This work should be found in every medical reference library. In such, and in the hands of the specialist and advanced student it will find its greatest use. As is recognized in the preface it is not a complete treatise of the pathology of the nervous system. The pathologist and the clinician will find it a valuable addition to their library as part of the reference material.

eral discussion and not under separate headings. Thus the reader may search the index in vain for the names of certain familiar diseases. Perhaps subsequent volumes may be added to the present series to fill in these gaps, which are in part due to the incomplete state of our knowledge.

An Experimental and Clinical Study of Pain in the Pleura, Pericardium and Peritoneum. By JOSEPH A. CAPPS, M.D., F.A.C.P., Professor of Clinical Medicine, University of Chicago, with the collaboration of GEORGE H. COLEMAN, M.D., F.A.C.P., Assistant Professor of Medicine, Rush Medical College. Foreword by ANTON J. CARLSON, M.D., Ph.D., Chairman of the Department of Physiology, University of Chicago. iv + 99 pages, 33 illustrations. The Macmillan Company, New York City, 1932. Price \$3.00.

This book is the result of the wise application of the experimental method of scientific medicine to the daily practice of the art. When opportunity was offered by openings into the great body cavities, a silver wire passed through a hollow trochar was used to explore the pleural covering of lungs, chest wall and diaphragm, noting the presence or absence of pain and, when present, the exact location and character of the pain experienced. By a similar procedure the pericardial sac was explored when tapping for effusion, and likewise the peri-

toneum. The results of twenty years' application of this method are recorded in this small book. It thus becomes a unique contribution to the study of the significance of the localization of pain and of referred pain. It is compactly presented, simply written, and adequately illustrated. It should be read by all concerned with the diagnosis of disease of the chest and abdomen.

Clio Medica VII Medicine Among the American Indians. By ERIC STONE, M.D., xv + 139 pages, 17 illustrations. Paul B. Hoeber, Inc., New York City, 1932. Price, \$1.00.

To American readers the seventh book in the Clio Medica series will prove of unusual interest. The convenient size of these low-priced medical historical monographs has already been commented upon in this section of the ANNALS. The present volume deals with the medical theories and practices of the American Indian. The material is presented in a highly interesting manner and the reading of this small volume will, for many, correct erroneous ideas about the intimate life of the Indian prior to the coming of the white man. Moreover, Indian Medicine had its own important effect upon the medicine of the pioneer white. Much of our medical folklore has an Indian background, and the Indian is said to have added 59 drugs to our modern pharmacopeia. This book is a good coat-pocket companion for a short railway journey.

College News Notes

Acknowledgment is made of the following gifts to the College Library of publications by members:

Dr. H. Sheridan Baketel (Fellow), Jersey City, N. J.—1 reprint.

Dr. I. D. Bronfin (Fellow), Denver, Colo.—1 reprint.

Dr. John E. Grewe (Fellow), Cincinnati, Ohio—1 reprint.

Dr. Philip B. Matz (Fellow), Washington, D. C.—1 reprint.

Dr. Leon L. Solomon (Associate), Louisville, Ky.—5 reprints.

Dr. Edgar F. Kiser (Fellow), Indianapolis, Ind.—1 reprint.

Dr. Carl A. Vischer (Fellow), Philadelphia, Pa.—1 reprint.

Dr. Hyman I. Goldstein (Associate), Camden, N. J.—2 reprints.

Dr. Norman Strauss (Associate), New York, N. Y.—1 reprint.

Dr. John H. Peck (Fellow), Boston, Mass.—1 reprint.
Member, American Association of Anatomists, President of the National Association of Anatomists.

At the recent annual meeting of the Medical Society of the State of North Carolina, at Winston-Salem, the following Fellows of the American College of Physicians gave papers as indicated

Dr Paul H Ringer, Asheville—"Modern Trends in the Management of Tuberculosis",

Dr S M Bittinger, Sanatorium—"A Brief Discussion, with Presentation of Several Types of Disease of the Lymphatic Glands Observed at the State Sanatorium",

Dr S D Craig, Winston-Salem—"Iodized Salt, its Common Usage and Results",

Dr I H Manning, Chapel Hill—"The Contributions of Biological Chemistry to Clinical Medicine",

Dr W T Ramey, Fayetteville—"Hypothyroidism",

Dr L B McBrayer, Southern Pines—"Tuberculosis in Early Adult Life and its Prevention",

Dr David T. Smith, Durham—"The Relation of Diet to Disease"

Dr O H Perry Pepper (Fellow), Philadelphia, Pa, was a guest speaker at this meeting

Dr M L Stevens (Fellow), Asheville, completed his term as President of the Medical Society of the State of North Carolina at its recent meeting

Dr Isaac H Manning (Fellow), Dean of the Medical Department of the University of North Carolina, Chapel Hill, was elected President-elect and will assume the office of President at the next annual meeting

Dr James B Bullitt (Fellow), Professor of Pediatrics at the University of North Carolina, was elected President of the North Carolina Association of Medicine at its thirty-first annual meeting at Wake Forest College

Dr W. C. P. McNeill (Fellow), Professor of Pediatrics, University of North Carolina, was elected President of the North Carolina Association of Medicine at its thirty-first annual meeting at Wake Forest College

lyn, was recently appointed Pediatrician to the Mary Immaculate Hospital, Jamaica, New York

Dr E Henry Jones (Fellow), Youngstown, Ohio, after pursuing postgraduate study in Dermatology and Syphilology, has abandoned his work in Internal Medicine and become Attending Dermatologist and Syphilologist to the Youngstown Hospital

Dr S Calvin Smith (Fellow), Philadelphia, Pa, spoke on "The Clinical Significance of the Irregular Pulse" at a joint meeting of the Columbia, Lycoming and Montour Counties Medical Societies held at Bloomsburg (Pa) Hospital, June 3

Dr Samuel M Feinberg (Fellow), Chicago, Ill, addressed the Carroll County Medical Society at Savanna, Ill, June 17, on "Respiratory Allergy"

Dr Curran Pope (Associate), Louisville, Ky, delivered an address before the Louisville Society of Medicine on June 2, his topic being "Personal Observation and Studies of Pyretotherapy"

Dr Louis F Bishop (Fellow) and Dr. Louis F Bishop, Jr (Fellow), both of New York City, addressed the American Therapeutic Society at its Baltimore meeting in May on "A Study of Vertigo or Syncope in Association with Cardiovascular Disease", with lantern slide demonstration of cases

Dr A W F Westhoff (Fellow), Richmond Hill, N Y, was recently appointed Consultant to the Staff of the St Cecilia Women's Hospital, Brooklyn

Dr W McKim Marriott (Fellow), Dean and Professor of Pediatrics, Washington University School of Medicine, St Louis, has accepted the visiting lectureship at the University of California Medical School for 1932-33

Dr Sidney J Shapiro (Fellow), San Francisco, Calif, has been made Associate Clinical Professor of Medicine at the University of California Medical School

Dr Oval N Bryan (Fellow), Nashville, Tenn, was elected President of the Middle Tennessee Medical Association at its meeting in May

Dr Lewellys F Barker (Fellow), Baltimore, Md, delivered the Commencement Address, May 31, at the University of Texas School of Medicine Commencement Day marked the dedication at the University of Texas School of Medicine of its three new buildings, including a medical laboratory, the John Sealy Hospital Outpatient Building and the Rebecca Sealy Residence for Nurses

The total cost of the three buildings was approximately \$2,500,000 The laboratory building contains laboratories for histology, embryology, pathology, anatomy and experimental surgery, in addition to a museum of surgical pathology, a museum of general pathology, a library and two large lecture halls The John Sealy Hospital Outpatient Building contains the administrative offices, x-ray department, surgical department, laboratories for basal metabolism and electrocardiography and clinics for ophthalmology, otolaryngology, obstetrics and gynecology, also laboratories, amphitheaters, mortuary room, animal houses, etc

Dr William A White (Fellow), Washington, D C, has been elected President of the International Congress on Mental Hygiene

Dr Charles F Martin (Master), Montreal, has been elected a Vice President

The second International Congress on Mental Hygiene will be held in Paris, France, during 1935

Dr Konrad E Birkhaug (Fellow), Associate Professor of Bacteriology, University of Rochester School of Medicine, Rochester, N Y, is in Paris studying at the Pasteur Institute He will also spend some time in the study of art A collection of water colors, bas-reliefs, masks and modeled figures by Dr Birkhaug were recently exhibited at the Art Center in Rochester

Dr Edward B Krumpholtz (Fellow), Philadelphia Pa and Dr Ward I MacNeil (Fellow), New York, N Y, were

elected President and Vice President, respectively, of the American Society for Cancer Research at the recent meeting of that organization

Dr Joseph M King (Fellow), Los Angeles, was installed as President of the California Medical Association at its recent meeting in Pasadena

Dr Andrew C Gillis (Fellow), Professor of Neurology, University of Maryland School of Medicine, Dr Maurice C Pincoffs (Fellow), Professor of Medicine, University of Maryland, and Dr Robert H Riley (Fellow), Director of the Maryland State Department of Health, all of Baltimore, have been appointed Consultants to the Baltimore Health Department

Dr Marcus W Newcomb (Fellow) Browns Mills, N J, was elected a Vice President of the Medical Society of New Jersey at its annual session in Atlantic City, June 17

Dr Howard T Phillips (Fellow) Wheeling, W Va, read a paper on "Diagnosis and Treatment of Prevalent Skin Diseases" at Logan, W Va, before the Logan County Medical Society on August 19

At the annual meeting of the fifth District Medical Society held at Baton Rouge, La, on July 14, Dr Lester J Williams (Fellow), of Baton Rouge was elected President and Dr Cecil O Lorio (Fellow) of Baton Rouge was elected Secretary Treasurer

On the scientific program were Dr Philip H Jones (Fellow) of New Orleans whose subject was "Some Considerations Related to Scrums Proteins and Idioms" and Dr Cecil Lorio (Fellow) of Baton Rouge who presented a paper on "The Nervous System and His Difficulties"

"The Newer Synthetic Drugs in the Treatment of Biliary Diseases" was the subject of a paper by Dr Samuel Weiss (Fellow), New York City who presented it at the International Congress of Internal Medicine at Vienna, Austria, Sept. 12-22, 1934

Dr Sidney A Slater (Fellow), Worthington, Minn, has been re-elected to the Directorate of the National Tuberculosis Association for a two year term

Dr William Egbert Robertson (Fellow), who has held the Chair of Medicine for many years at Temple University School of Medicine, has been appointed Emeritus Professor of Medicine, and will devote much of his time to medical research. Dr John A Kolmer will succeed Dr Robertson as Professor of Medicine, beginning with the autumn semester. Dr Kolmer has resigned as Professor of Pathology and Bacteriology at the Graduate School of Medicine of the University of Pennsylvania

At the regular meeting of the Western Oklahoma Medical Society, at Clinton, Okla, July 19, Dr Lea A Rielv (Fellow), Oklahoma City, and Dr Carroll M Pounders (Fellow), Oklahoma City, delivered addresses on "Some of the Complications of Diabetes" and "Diarrheas of Infants and Children", respectively

The University of Oklahoma conducted a postgraduate medical course in Degenerative Diseases for a period of four weeks during the summer. Dr Warrin Langston (Fellow), Oklahoma City, offered the course in Generalized Arterial Disease, Hypertension and Myocardial Disease, Dr P T Bohan (Fellow), Kansas City, offered the course in Coronary Disease and Angina Pectoris, Dr C J Fishman (Fellow), Oklahoma City, offered the course in Vascular Disease of the Brain, Dr Lea A Rielv (Fellow), Oklahoma City, offered the course in Peripheral Vascular Disease and Chronic Rheumatic Disease, Dr A W White (Fellow) and Dr J T Martin (Fellow), both of Oklahoma City, offered the course in De-

generative Disease on Basis of Food Deficiencies, Pellegra, Pernicious Anemia, etc

Dr John H Peck (Fellow), Des Moines, Ia, headed a delegation of sixty American physicians to attend the Eighth Session of the International Union against Tuberculosis at the Hague and Amsterdam, September 6-9, 1932

Dr R H Kampmeier (Fellow), formerly Instructor in Internal Medicine at the University of Michigan Medical School, and more recently Internist at the Pueblo Clinic, Pueblo, Colo, has accepted an appointment as Assistant Professor of Medicine at the Louisiana State University Medical Center, New Orleans

Dr Frederick K Herpel (Fellow), West Palm Beach, Fla, was recently elected Vice President of the Florida Radiological Society

Dr Cecil O Lorio (Fellow), Baton Rouge, La, and Dr Maud Loeber (Fellow), New Orleans, La, were elected President and Secretary-Treasurer, respectively, of the Louisiana State Pediatric Society at its last meeting

Dr John A McIntosh (Fellow), San Antonio, Texas, was recently elected President of the Texas Neurological Society

Dr Charles G Jennings (Master), Detroit, Mich, in June was the recipient of the degree of Doctor of Science from the College of the City of Detroit

Dr Delvan MacGregor (Fellow), Wheeling, W Va, was elected President of the West Virginia Medical Association at its annual meeting in June

Artificial Fever Produced by the Short Wave Radio and Its Therapeutic Application

By C F TENNEY, M D, F A C P, *New York, N Y*

FOR the past fifteen years we have been interested in producing artificial fever as a therapeutic agent in the treatment of diseases of the peripheral circulation and arthritis by injecting a foreign protein intravenously following the work of Petersen, Miller, and Lusk. This injection produces a chill within thirty minutes to an hour, followed by a rise in temperature of from two to five degrees, this in turn is followed by a sweat. The blood changes are an increase in the number of white blood corpuscles, as well as in the polymorphonuclears, and a slight variation in the chemical constitution of the blood and in blood pressures. In the treatment with the foreign protein the majority of cases complain that the chill is the most uncomfortable part of the reaction. It is also with some anxiety that a foreign protein is injected into the circulation.

In former times fever was induced by the application of external heat to the body, such as the tub-bath, hot packs, the electric cabinet, thermal baths in so called healing waters, and mud packs taken from mineral springs.

Presented at the San Francisco meeting of the American College of Physicians, April 6, 1932

From the Medical Service of the Fifth Avenue Hospital, New York City

It is common practice in England today to wrap the patient in hot moist blankets, putting on more blankets to lessen heat radiation and thus produce an increase in body temperature.

Doctors have observed that patients suffering from a chronic ailment are sometimes benefited by an intercurrent infection associated with a chill, fever, and sweat.

A new adjunct in the treatment of paresis in the past ten years has been introduced by inoculating the patient with malarial parasites, which in turn produces chill, fever, and sweat but with the detrimental effect of destruction of the red blood corpuscles, the subsequent weakening of the patient and later having to cure the malaria. This treatment has however been most beneficial to these cases.

A newer form of producing hyperpyrexia is with the application of large diathermy plates to the trunk of the body, thus producing artificial fever. However, it is not a very comfortable jacket to wear.

Dr W R Whitney, Director of the Research Laboratory of the General Electric Company, has conducted the men working in the field of short wave transmitter had this experience. He was interested in the cure of paresis by Wernicke's disease.

thought possibly a machine could be developed which would produce artificial temperature, which could be controlled at will and might be of benefit in these cases. The outcome of his observation has been the radiotherm.

The essential difference between diathermy and the short wave radio is that the waves of diathermy demand that the electrodes be placed in good contact with the skin, while the ultra-short waves act by having the plates near the body with an intervening air layer between. The diathermy waves have the least effect on the bones and joints and most on the muscles, whereas the ultra-short waves act on all of these as well as on the deep-seated organs and can be directed to a considerable degree.

The description of the short wave radio as given by Carpenter and Page¹ may be repeated here:

"Since 1928 special types of apparatus have been designed by the Research Laboratories of the General Electric Company and used experimentally in an endeavor to cause a fever in man rapidly, without great discomfort to the patient and to a degree high enough to be of value. The equipment used has been constructed on the same principle as a short wave radio transmitter, with the exception that the energy is concentrated between the two condenser plates instead of being directed from an aerial. The heating current is a vacuum tube oscillator. This high frequency oscillator is composed of two tuned circuits operating at a frequency of 10,000 to 14,000 kilocycles, the energy being concentrated between the plates of the condenser instead of being radiated from an aerial. The electrodes are 30 inches by 20 inches by 1/8 inch and are covered with hard rubber plates 30 inches by 20 inches by 1/4 inch to prevent arcing should the patient or attendant come in contact with the plates. In this field of undamped waves between the plates, there is a rapid alternation of 3,000 volts drop of potential. The greatest heating has been obtained by the use of a 30 meter wave that oscillated 10,000,000 times per second between the plates. This is the same type of short waves that is used in broadcasting long distances."

"The condenser plates are aluminum, 28 inches by 18 inches by 1/8 inch and are covered with hard rubber plates 30 inches by 20 inches by 1/4 inch to prevent arcing should the patient or attendant come in contact with the plates. In this field of undamped waves between the plates, there is a rapid alternation of 3,000 volts drop of potential. The greatest heating has been obtained by the use of a 30 meter wave that oscillated 10,000,000 times per second between the plates. This is the same type of short waves that is used in broadcasting long distances."

We have been fortunate in having one of these machines presented to us at the Fifth Avenue Hospital by Mr. Rex Cole of the General Electric Refrigerator Company.

We have recently been using, also, a small portable machine through the courtesy of the General Electric Company. It is like the large machine in principle but the plates are smaller and are fastened to movable arms so that local heat may be given to any part of the body. We have been using it in the treatment of pelvic inflammatory conditions, arthritis, pneumonitis, bronchiectasis, and circulatory diseases of the extremities. This local heat may increase the body temperature one degree. A more detailed report will be given at a later time, as we have had this machine in operation for only two months, no other machine of this kind is being used in this country, although work is being done in Germany with the same type of machine.

In the original use of the short wave radio machine in the research laboratories at Schenectady,¹ the University of Rochester,² the University of Toronto,³ the Albany Medical College,⁴ the New York State Psychiatric Institute,⁵ and the Boston Medical Clinic, Santa Barbara, considerable experimental

FIG 1 High-frequency heater for therapeutic use

FIG 2 High-frequency heater without top to show internal components

work was done upon animals, as well as on the heating of fluids at different concentrations and on the heat effects upon bacteria. First efforts were directed toward demonstrating that the activity of the waves is harmless. This was done by subjecting white rats to a temperature of 105° daily for 120 days; these rats developed and had healthy litters the same as the controls, showing no apparent detrimental effects. Similar experiments were done on rabbits. Other research work was done to find out what happens when a solution such as sodium chloride in various concentrations was heated in the field of oscillation.

"It was found that with increasing concentrations of a simple electrolytic solution such as one of sodium chloride, the rate of rise in temperature increased rapidly from water to a maximum at a concentration of 0.0045 normal sodium chloride. In higher

concentrations it decreased. At 4.0 normal it was little more than that of pure water."

It is possible that the heating effect of these waves may also be selective in character and it has been proven by further experimentation in animals with the needle thermometer, that the temperature of the liver, heart, kidneys, spleen, and muscles, corresponds to the rectal temperature.

In the heating of the human body the patient is placed above the radio between the two plates and may be covered with a celotex cabinet with hot-air dryers blowing to evaporate the perspiration, or he may be placed between the plates wrapped in blankets.

We have found in our work that the patients are more comfortable and the temperature rise is more rapid if the following methods are observed in preparation for the treatment. Small

Fig. 1. Patient in position for treatment between plates.

superficial blisters may occur and are apparently due to the heat from the arc as well as to the drops of perspiration that are heated by the arcing. We request all our patients to buy a cotton and wool union suit that fits closely to all parts of the body, thus absorbing the perspiration in an even manner, they are then wrapped in a sheet, and blankets are snugly wrapped about them, covering the entire body except the head. If the patient complains of a burning sensation in any part of the body, the switch is turned off and the nurse strokes over that part so as to absorb the perspiration. The burning sensation ceases at once. Another point to keep in mind is the nervous anxiety of the patients in being confined in the blankets, especially after their temperature is 103° or above. Nausea may be complained of, but we have found it only in nervous patients. Still another point, but of less importance, is the placing of the wooden frame in front of the plates so as to prevent the possibility of anyone's coming within the wave length near them. In other words a person other than the patient may absorb considerable additional energy from the outfit if he comes too close to it, thus overloading the generating tubes.

The patient is placed on the canvas-stretched wooden frame between the plates so that the trunk of the body comes within the range of the plates. These are placed so that the waves oscillate through the body from one side to the other. The plate distance can be varied but as a rule has been kept at 30 inches. By applying the plates in this manner and having the body wrapped closely in blankets, it is heated rapidly

without causing great discomfort. We have raised the normal rectal temperature of 99.6° F to 104° and 106° in from 60 to 80 minutes. It is believed that the development of heat is due to the resistance of the body to the conduction of the current between the surface adjacent to the opposed plates as well as to the salt content of the blood.

In raising the temperature in the manner described, the greatest amount of resistance is found in the internal organs, such as the liver, heart, spleen and kidneys, due to their large blood supply.

When the desired temperature is reached it may be maintained in several ways — (1) By increasing voltage, (2) by increasing plate distance, (3) by applying more blankets. When this temperature is reached we remove the patient in the blankets to his bed, placing more blankets and hot water bags about him so that the heat may be maintained from three to four hours longer, or we placed shellacked paper cabinets heated with electric light bulbs over the patient. In this way we may raise the body temperature even higher. The temperature of a thin person rises more rapidly than that of a fat one.

It is necessary to read rectal temperatures at least every fifteen minutes after 103° is reached. It is particularly important that these temperatures be observed because if the patient should have a disturbance of the thermal center of the brain, the temperature might rise to 109° and death follow. If the temperature should go higher than desired after the patient is in bed, a hot bag may be applied to the head, the blankets are then gradually removed, a cool sponge bath is given, and if the

crease comes, according to his findings, at about the ninth hour after treatment, returning to the normal level at about the twentieth hour. Our counts seem to indicate the same findings. The clotting factors show a definite increase in platelets. In no instance was blood viscosity increased at the height of fever in those cases where the loss of body fluids was replaced by a large fluid intake. Of thirty-three cases in which blood viscosities were taken, eighteen were arthritics. All of these ran a viscosity somewhat higher than normal. As the temperature rose in fourteen, viscosity dropped from 0.1 to 1.5 points, two cases remained unchanged and in four where fluid was not given there was an increase. One patient receiving a 5 per cent sodium chloride solution intravenously had a subnormal viscosity. In one case treated with sodium citrate intravenously before treatment, the viscosity was decidedly lowered. The blood sedimentation was faster and there was an increase in the blood plasma in these cases. The basal metabolic rate in one of the arthritic cases was minus twenty-nine before treatment; at a temperature of 104° it

was plus six, and after treatment, plus one.

In examining the circulation, microscopic study of the capillaries of the nail beds showed an increase in the size and number of capillaries during the height of the temperature. There is an increase in the oscillometer readings of the deep circulation, (table I) and an increase in the skin temperatures, as well as an increase in the size of the wheal in the histamine skin tests (table II) in some of the cases of occlusion of the blood vessels of the lower extremities. Another fact that we have noted is that the treatments seemed to have more of a tonic effect than a debilitating one even though the temperature is high and the sweating considerable. There is a loss in weight in the early treatments which is gained as the treatments progress.

SUMMARY

We have been very much encouraged in our work with the High Frequency Heater as an aid in treatment. Arthritis (table III) has become such an economic problem that any aid in the care of this disease is of great value. We

think as Dr Ralph Pemberton does, that arthritis is in part a disease of the circulation and that any one of several infective agents may be the causative factor in many of the cases. Heat in almost any form is excellent. If a patient is undergoing a course of vaccine therapy under the direction of his physician and is referred to us for radiothermy, the vaccine is continued. The greater number of our cases have been treated with radiothermy and massage, with the preliminary step of removal of foci of infection.

In our use of the High Frequency Heater in the treatment of syphilis, we have treated primary, secondary, and tertiary cases in conjunction with the regular antileptic treatments. The results of the treatment (table IV) in the primary and secondary cases, have been good, the primary lesion and secondary rash disappeared with unusual rapidity. In some of the cases whose Wassermann reaction was strongly positive, after one treatment the reaction has been returned as weakly positive. Our best results have been obtained in the tertiary cases especially in those involving the central nervous system.

"Doctor Hinsie's observations on 136 patients with general paralysis, one-half of

whom had malarial treatment and the other half radiothermy treatments, show that the clinical signs of improvement have been equal in both. The laboratory findings, however, do not show signs of improvement as rapidly in the radiothermy treated cases as in the malarial. The explanation of this is that it takes longer for laboratory findings to change than it does for clinical manifestations."

If a temperature of 106° is maintained from two to four hours in cases of gonorrheal infection, such as urethritis, arthritis, and pelvic inflammatory disease, it acts almost as a specific. As the thermal death point of the gonococci is supposed to be around 104° , they are probably destroyed by the heat.

In diseases of the circulation of the lower extremities, we have used both the general and local forms of therapy. In the few cases of intermittent claudication of the arteriosclerotic type we have treated, there is improvement, pain comes on later in exercise, and there is an increase in the arc of the oscillogram readings. In thrombo-angitis obliterans in younger individuals we have not had sufficient time nor cases to draw definite conclusions. In three cases of Raynaud's disease treated, the results compare favorably with those of foreign section operations.

29 E R	Primary and secondary syphilis	3 weeks	Chancre of lip 1 ch	Symptom free
30 A B	Primary syphilis	8 months	Pain in legs weakness of gait	Improved
31 O S	Tabo-paresis	?		

On the other eight cases, we have been unable to get full improvement

CONCLUSIONS

1 We feel that we are using a form of artificial fever which is less hazardous than that produced by intravenous injections, and these conclusions have been reached after giving over one thousand treatments

2 It is a form of fever which is entirely within the control of the operator, if kept below 107.°

3 There is very little discomfort to the patient

4 Application is simple

5 We believe that this method of producing artificial fever is superior to other methods, and that the therapeutic results obtained are better.

Laboratory studies were conducted by the following

Pauline VanAlstyne, tests on blood viscosity,

Charlotte Caduff, blood sedimentation tests,

Katherine Oblander, blood counts and blood chemistry

A Comparison of Orthodiagraphic and Teleroentgenographic Measurements of the Heart and Thorax

By PAUL D. WHITE, M.D., F.A.C.P., and PAUL D. CAMP, M.D., *Boston, Mass.*

ORTHODIAGRAMPHY was first introduced by Moritz thirty years ago. In his first article on this subject (*Munch. med. Wchnschr.*, No. 29, July 17, 1900) he explains that because of the fact that roentgen rays originate from a point on the anti-cathode and from this point radially diverge, the shadow which they produce will necessarily be distorted in triangular proportion to the distance of the object from the anti-cathode. The teleroentgenogram will always be larger than the object. In order to overcome this error Moritz devised a method by which he could cut out all the rays except the true central or parallel ray. With this central ray he outlined the silhouette of the heart and chest wall. Since there is no divergence in the central ray as it is moved tangentially around the silhouette one obtains the exact size of the frontal plane of the heart and chest wall. For detailed description of the technique and apparatus used by Moritz one should consult the original article. Suffice it to say here that the tube was movable and that the outline of the shadow cast by the heart and chest wall from the central ray was directly recorded on the fluorescent screen.

In the early work on determination of the heart size by roentgen ray photography the distances of the patient from the tube were much less than the distances which are used today. Rosenfeld in 1897 used 40 cm., and Gotch in 1898, one meter. These distances were not satisfactory and therefore Kohler in 1905 introduced the use of the two meter distance (teleroentgenography). Even from this distance, however, the rays are not parallel when they reach the object studied and hence there is still some distortion. Van Zwaluwenburg stated that "Even at nine feet the shadow on the plate usually exceeds that of the orthodiagram by from 6 to 15 per cent. The same error appears in the outline of the chest wall." Hodges also expresses the opinion that "some distortion of the shadow exists at 9 feet".

All authorities agree that the orthodiagraphic measurements are more accurate than the teleroentgenographic with perfect technique in the use of both methods. Groedel has even gone so far as to say "But when we wish to determine the form, position, and size of the heart, observations made by the orthodiagraph are absolutely correct."

In spite of the recognition that the

thorities of the greater accuracy of the orthodiagram in actual measurements as compared to the teleroentgenogram (or "six or seven foot" plate or film) most physicians in this country do not appreciate this fact and are quite unfamiliar with the simplicity and value of the orthodiagraphic method. Hence we have made a brief study of the results of a comparison of orthodiagrams and teleroentgenograms of the heart and great vessels which we are presenting herewith.

Our series consists of twenty-two cases. Ten of these had hearts of normal size, ten had enlarged hearts, the twenty-first case was one of luetic aortic aneurysm and the twenty-second case was one of pericarditis with effusion.

For the sake of practical application of this study the orthodiagrams were made by ourselves* while the teleroentgenograms were made at the same time of day within a day or two in the ordinary routine manner by the X-ray Department of the Massachusetts General Hospital, and we would like herewith to express our thanks for the cooperation given us in this study. With closely controlled records made simultaneously by both methods in the same phase of respiration greater accuracy

and a nearer approach to theoretical expectations would be possible than we secured here, but the advantage of comparison of the two methods carried out independently and in a routine way would thereby have been lost.

The usual measurements were taken, that is, transverse diameter (T) which is the sum of the perpendicular distance from the midline to the extreme right border of the heart (MR) and similar distance to the extreme left heart border (ML), longitudinal diameter (L), width of the great vessels just above the heart shadow itself (GV), the internal horizontal diameter of the chest (Th), and the cardiothoracic ratio (CTR) which is determined by dividing the transverse diameter of the heart (T) by the internal transverse diameter of the thorax (Th). The cardiac areas (A) were computed with the use of a planimeter, these area measurements cannot be said to be free of error as the outline of the heart had to be established somewhat arbitrarily at the upper and lower borders by joining the ends of the right and left borders of the heart shadow by slightly convex lines. The teleroentgenograms were made with the customary technique, the target of the tube being seven feet from the photographic film with which the anterior chest wall of the subject was in contact. We, ourselves, made all the measurements on both orthodiagrams and teleroentgenograms.

The measurements of the entire series are given in the large table.

To determine how large an error may enter into the figures by simple variation in the measurements of the heart size and chest size of an individual repeated on different days we

*The orthodiagrams were made with the Reflex heart vertical fluoroscope with special attachment which records the heart and thoracic shadows by means of a special paper jacketed from a sheet of black paper. The film is placed in the jacket and the heart and thoracic shadows are recorded exactly as they appear. There is a small amount of magnification, but it is constant and can be corrected for by a simple calculation. The magnification is about 10%.

orthodiagraphed two persons twice at an interval of one day in one instance and of three days in the other. As in the case of the routine study of the special series, we were careful to trace and measure as accurately as possible and under the same circumstances at the same time of day. The measurements in centimeters in these two individuals were as follows:

		MR	ML	T	L	GV	TH	CTR	ARI A
S McG	First day	38	90	128	132	50	24.5	52.2%	92.4
	Second day	37	92	129	135	50	24.4	52.8%	97.7
R P B	First day	38	75	113	132	40	23.0	49.1%	97.3
	Second day	38	75	113	132	40	22.8	49.5%	91.2

Thus it is evident that one may attain a high degree of accuracy in measurement. The least constant and therefore least satisfactory comparative measure-

ment proved to be that of area, this was in large part due undoubtedly to the need of filling in arbitrarily upper and lower borders of the heart shadow.

I THE NORMAL GROUP

The group of normal sized hearts is from healthy individuals (Figure 1 shows the tracings in Case 1.)

1 Transverse diameter. The trans-

verse diameter was greater by tele-roentgenography than by orthodiagraphy in all cases, the greatest difference being 1.4 cm., and the smallest differ-

Figure 1, H.B.S. Group I, Case 1.

FIG 1 Orthodiagram (solid line) and tracing of teleroentgenogram (dotted line) of borders of heart, great vessels, clavicles, and diaphragm. The vertical margins of the lateral walls of the thorax of H.B.S. Case 1 of Group I are also shown. A vertical midline is also represented. Records made during quiet respiration. For details of actual size. See table for measurements.

ence 0.4 cm. The teleroentgenogram averaged about 1 centimeter (0.9 cm) greater than the orthodiagram in the transverse diameter of the heart in these normal individuals

2. Median right (MR) The median right diameter by teleroentgenographic measurement was less than that by orthodiagraphic measurement four times, equal to the orthodiagraphic once, and greater five times, the greatest difference between the orthodiagram and the teleroentgenogram was 1.7 cm. The teleroentgenogram averaged 0.2 cm greater than the orthodiagram in this MR distance

3. Median left (ML) The teleroentgenogram showed a greater median left diameter in all except two cases. The least difference in measurements was when the teleroentgenogram was 0.2 cm less than the orthodiagram; the greatest was when the teleroentgenogram was 2.0 cm greater than the orthodiagram. The teleroentgenogram averaged 0.7 cm greater than the orthodiagram in the ML distance.

4. Longitudinal (L). The longitudinal diameter, i.e., from the point of junction of right auricle and aorta or superior vena cava to the apex, was found in each case to be greater by teleroentgenography than by orthodiagraphy, the greatest difference being 2.6 cm, the least 0.6 cm; the average was 1.5 cm

5. Great vessels (GV) The greatest transverse width across the heart was found in the anteroposterior diameter and the teleroentgenographic measurement was greater than the orthodiagraphic measurement in every case. The greatest difference was 1.1 cm, the least 0.2 cm; the average was 0.5 cm

(Th) we found a greater degree of difference in the results of the two methods, here the teleroentgenograms averaged 2.5 cm more than the orthodiagrams, and the teleroentgenograms gave larger measurements in every case.

7. Cardiothoracic ratio (CTR, that is, T divided by Th). The cardiothoracic ratio (percentage) in seven of the ten normal sized hearts presented a lesser value by teleroentgenogram but in the total of ten cases averaged only 0.9 per cent less than in the orthodiagram. The greatest difference occurred in a case which showed a cardiothoracic percentage by teleroentgenogram 3.3 per cent less than by orthodiagram

8. For the cardiac area (A) the square centimeter was chosen as the unit of measure and in all of the normal cases the teleroentgenographic area was larger than the orthodiagraphic. The greatest difference was of 41.0 sq. cm and occurred in two cases; the average difference was 22.2 sq. cm. Expressing this difference in terms of percentage of the orthodiagraphic area so that we may have a clearer idea of the comparison, we find that the area by teleroentgenogram was greater than that by orthodiagram by 44.0 per cent in an extreme case while the average difference in area size was 24.7 per cent

From these measurements in the normal cases it is evident that, as was to be expected, the greater the measurements the greater is their magnification by teleroentgenogram. The discrepancies in a few of the MR and ML measurements are to be accounted for by a failure in technique; that is, the measurements by orthodiagram and by teleroentgenogram were not taken on the same plane.

roentgenogram are taken without maintaining the heart in exactly the same position. A slight rotation or lack of exact centering will affect the relative lengths of MR and ML, without affecting T. Moreover, the teleroentgenograms were made at varying phases of quiet breathing and of the cycle of cardiac contraction while the orthodiagrams were drawn so far as possible in midrespiration and in a phase midway between systole and diastole, this may easily account at times for a discrepancy of a few millimeters. Finally it is not possible to make, in a practical way, measurements by either method that are exact to a millimeter or two, as indicated by comparing successive orthodiagrams or successive teleroentgenograms. This factor alone readily accounts for some of the individual discrepancies but the average

orthodiagraphic measurements are always less than the average teleroentgenographic measurements.

II GROUP OF ENLARGED HEARTS

Figure 2 shows the tracings of Case 1 of this group.

1 Transverse. In the enlarged hearts we found that the teleroentgenographic transverse measurements were greater in all but one of the ten cases, the least difference being 0.6 cm. and the greatest 1.8 cm., while the average showed T by orthodiagram less than that by teleroentgenogram by 1.1 cm.

2 Median right. The median right measurement as recorded by teleroentgenogram was greater than the orthodiagraphic measurement in seven cases, twice the two methods gave equal results and once the teleroentgenogram gave less. The greatest difference was

Figure 2, F. O. Group II, Case 1.

* Area of heart above the line and area of aneurysm below the line
O Same case with heart measurements after pericardial paracentesis.
† Same individual (No. 3 of 1st group) in quiet respiration ‡ Same individual with deep expiration.

1.1 cm, the average was 0.4 cm greater by teleroentgenogram.

3 Median left In all except one case the median left diameter was greater as obtained by teleroentgenogram, in that one case the ML by teleroentgenogram was 0.3 cm less than by orthodiagram. The average difference was 0.7 cm greater by teleroentgenogram.

4 Longitudinal The teleroentgenographic measurements of L were greater than the orthodiagraphic measurements in all cases, the greatest difference recorded by the two methods was 3.3 cm and the least was 0.3 cm. The teleroentgenographic measurements of L averaged 1.2 cm greater than the orthodiagraphic measurements.

5 Great vessels In the measurements of the great vessels the two methods gave the same results in one case, in one case the teleroentgenogram showed G V to be 0.2 cm less, in another case 0.3 cm less than shown by orthodiagram, and in seven cases this measurement was greater by teleroentgenogram, the greatest difference being 1.5 cm, the average difference in the ten cases was 0.4 cm greater by teleroentgenogram.

6 Thorax In all ten cases the teleroentgenographic intrathoracic diameters were greater, the greatest difference was 4.6 cm while the least difference was 1.6 cm. The average obtained by the teleroentgenogram was 2.8 cm greater than that of the orthodiagram.

7 Cardiothoracic ratio The results given are expressed as percentages of the transverse cardiac diameter as compared to the internal diameter of the

thorax. The teleroentgenogram showed a smaller percentage in eight cases, an equal percentage in one case, and a greater percentage in one case. The CTR by teleroentgenogram averaged 2.5 per cent less than that by orthodiagram.

8 Area In the enlarged hearts we found that the actual difference in areas as recorded in square centimeters was well-marked. The teleroentgenogram gave a larger area in every case. The greatest difference in the two methods was in a case in which the teleroentgenogram showed 46 sq cm more area than did the orthodiagram, in the case in which the least difference occurred the area by teleroentgenogram was 4 sq cm greater. The teleroentgenographic heart area averaged 25.4 sq cm greater than that by orthodiagram. Again expressing the results in percentages, we found the greatest difference in a case in which the teleroentgenographic area was 26.2 per cent greater than the orthodiagraphic area and in the case showing the least difference the teleroentgenographic area was 2.7 per cent greater. The teleroentgenographic area averaged 14.9 per cent greater than that by orthodiagram.

III SPECIAL CASES

A. Aortic Aneurysm of the Aorta

In this case (figure 3) the diameter of the heart and the aneurysmal sac furnish an interesting comparison. The orthodiagraphic measurements were as follows: (a) Diameter of aneurysm (frontal plane silhouette) 10.2 cm; (b) transverse diameter of heart 11.5 cm; (c) heart area 94 sq cm, and aneurysmal area 81 sq cm. The teleroentgenographic measurements were

(a) Diameter of aneurysm, 10.8 cm ,
 (b) transverse diameter of heart, 12.9 cm ; (c) heart area, 113 sq cm ; (d) aneurysmal area, 88 sq cm The reader is referred to the table for more detailed measurements

B Pericarditis with Effusion and later Artificial Hydropneumopericardium

In this case it is interesting to compare (1) the diameter of the cardiac shadow before a pericardial paracentesis had been performed orthodiagraphic transverse diameter, 20.5 cm , teleroentgenographic transverse diameter, 24.5 cm * (2) the diameter of the pericardial sac after air had been injected orthodiagraphic transverse diameter, 18.6 cm , teleroentgenographic transverse diameter, 19.8 cm Then contrast the two groups of measure-

ments with (3) the true diameters of the heart observed during the state of artificial hydropneumopericardium, orthodiagraphic transverse diameter, 12.4 cm , teleroentgenographic transverse diameter, 13.6 cm

C Case showing Effect of Respiration

The detailed measurements in this case are presented in the table 3a shows the measurements obtained during normal quiet respiration, 3b shows those obtained during full inspiration (figure 4) , and, finally, 3c those show-

*This unusually large difference of 4 cm between the orthodiagraphic and teleroentgenographic transverse diameter measurements is due in part to the large diameter itself and in part to exaggeration resulting from a difference in the shape of the pericardial sac due to a somewhat lower position of the diaphragm in the case of the teleroentgenogram

Figure 3. E.N.S. Group III, Case 1.

Figure 4. P.D.C. Group III Case 3.
(*Full Inspiration*)

FIG 4 Orthodiagram (solid line) and teleroentgenogram (dotted line) of P.D.C. Case 3 of Group III at the height of deep inspiration. Reduced to $\frac{1}{4}$ actual size. See table for measurements.

Figure 5 P.D.C. Group III Case 3.
(*Full Expiration*)

FIG 5 Orthodiagram (solid line) and teleroentgenogram (dotted line) of P.D.C. Case 3 of Group III at maximum full expiration. Reduced to $\frac{1}{4}$ actual size. See table for measurements.

ing the results of full expiration (figure 5). The measurements obtained during quiet normal breathing fit about halfway between the two extreme phases of respiration. The transverse heart diameters show a difference of 1.4 cm, 0.9 cm, and 1.3 cm in the respective phases of respiration (quiet breathing, full inspiration, and full expiration), as recorded by the two methods, the teleroentgenographic record being greater in each case. The intrathoracic diameter showed marked variations with respiration, the diameter by orthodiagram at full inspiration being 28.5 cm and during full expiration 25.0 cm, as compared with 29.0 cm and 27.0 cm respectively when recorded by the teleroentgenogram. The greatest variation in cardiothoracic percentages was shown by the orthodiagram as follows: full inspiration 40.3 per cent, full expiration, 59.0 per cent. The areas also showed marked changes according to the phase of respiration and the methods used, here again the orthodiagram showed the most marked difference between 88 sq. cm in inspiration and 112 sq. cm in expiration.

From this it seems that for cardiac measurements quiet breathing is preferable to either full inspiration or full expiration. It was very difficult for us to insure that we were obtaining readings exactly the same phase of deep respiration, especially at the extreme of expiration. Since the respiratory excursion was not equal, the thoracic diameter was not equal. The teleroentgenographic measurements were made at the same phase of respiration, and the measurements were more uniform. The orthodiagram measurements were made at the extreme of inspiration and expiration, and the measurements were more uniform.

SUMMARY AND CONCLUSIONS

We have presented herewith, first, a brief note on the introduction of orthodiagraphic and teleroentgenographic methods for obtaining cardiac and thoracic measurements, and second, measurements with each of these methods in a series of twenty-two individuals, ten normal healthy persons and twelve with abnormalities of heart, aorta, or pericardium. The results may be briefly summarized as follows:

In each of the diameters measured the teleroentgenographic average was greater than the orthodiagraphic average, and, as would be expected, the thoracic measurements showed a greater difference than the cardiac measurements. The transverse diameter of the heart averaged about 1 centimeter greater by teleroentgenogram than by orthodiagram (with an extreme difference of 1.8 cm.). The cardiothoracic ratio (percentage) was essentially the same by orthodiagraphy and by teleroentgenography in both normal and abnormal groups, averaging only 17 per cent greater by orthodiagraphy in the combined series of 10 normal and 10 enlarged hearts (0.9 per cent greater in the first group and 2.5 per cent greater in the second group). The absolute and percentage differences in area showed the teleroentgenogram greater than the orthodiagram in all cases of both groups. The absolute difference in area in the group with normal hearts averaged 22.2 sq. cm. greater and in the group with the enlarged hearts 25.4 sq. cm. greater; the teleroentgenographic area was greater than the orthodiagraphic area in the first group by 21.7 per cent and in the second group by 14.9 per cent.

That the differences between the orthodiagraphic and teleroentgenographic measurements given here are not to be accounted for by simple variations in an individual's heart size and chest size at different times has been proved by two findings: first, the consistently greater measurements by the teleroentgenogram, and second, control measurements of the same cases by the same method on different days but under the same conditions.

We have included in this study measurements of an aortic aneurysm and of a distended pericardium respectively, and additional measurements of one of the normal cases to demonstrate the striking contrast between the effects of full inspiration and of full expiration on the cardiac and thoracic measurements.

We have found, as was to be expected, that the orthodiagraphic method gives smaller measurements of cardiac and thoracic diameters than does the teleroentgenographic method and that the larger the object studied the greater the error due to divergence when the teleroentgenogram (seven foot plate) is

used. Since the ratio of magnification is always the same, however, in the teleroentgenogram, we should theoretically find the cardiothoracic percentage equal by the two methods. In our series of cases there was found a very slight difference in the ratios by the two methods which may be said to fall within the error for the measurements themselves. The greater cardiac area measurement by teleroentgenogram is a uniform finding and averaged 15 to 25 per cent in our cases.

Thus, in giving roentgen measurements of cardiac and intrathoracic diameters and of cardiac area it is essential to state whether these measurements are made by orthodiagram or by teleroentgenogram. The difference between the results of the two methods is great enough to render direct comparison misleading, and it is of course not right for those using the teleroentgenographic measurements (such as are used widely in the United States) to check such measurements against those recorded in tables based on orthodiagraphy (such as are standard throughout Europe).

A New Percussion Technic

By FRANK SMITHIES, Sc D , M D , M A C P , *Chicago, Illinois*

DURING the World War, when a member of a "draft-board team", the writer was, of necessity, compelled to examine physically a great number of candidates over a period of many months. In percussing thoraces, particularly by the ordinary mid-finger of one hand (hammer) to mid-finger of the other hand (pleximeter) method, a few hours' work resulted in a very sore dorsal surface of the pleximeter finger, even when the nail on the "hammer finger" was kept short, shaped broadly and smoothed by means of the emery stick. The joint of the hammer finger not rarely became swollen and painful and the extensor muscles and wrist of that hand ached long after the examining session. Muscle cramp resulting from over-use, caused work to be difficult and at times inaccurate.

As a consequence of experience gained in this work upon prospective soldiers and later in the handling of considerable material when teaching medical students a method of percussion entirely different from that commonly known and practiced, was developed. This method proved of such advantage that it has no dates in its history. It is a simple, efficient, and accurate method of percussion, the

advantages over the commonly employed percussion technic

In brief, the percussion technic employed is as follows

The pleximeter finger (or fingers) is placed upon the thorax or whatever body section is to be percussed, in the usual manner. The pleximeter finger (or fingers) is pressed firmly or lightly upon the body wall, accordingly as superficial or deep percussion is desired (Figure 1). The striking "hammer" is arranged by crossing the flexor surface of that portion of the second finger beyond the last interphalangeal joint of the percussing hand over the extensor surface of the index finger of the same hand, so as to have it cover practically the whole nail surface and that part of the index finger distal to the last interphalangeal joint. Then, by a quick, snapping movement, the second finger is slid from the index finger so as to strike forcibly the extensor surface of the "pleximeter" finger (or fingers) of the other hand (Figure 2). A little practice in so snapping apart the index and second fingers of the "hammer" hand, readily enables one to strike a considerable "sawtooth" and rounding stroke upon the pleximeter. Accordingly as the "hammer" finger are snapped apart the varying degree of interphalangeal joint quickly or slowly flexed and extended, the pleximeter

The smooth surface of the finger nail of the index finger allows very free "snapping" and results in blows which evoke fine, resonant notes. Particularly well do such tones serve when patients are being examined before a considerable group.

In carrying out this percussion technic, body surfaces — chest, etc. — are covered just as they are when using finger-tip (hammer) to extensor surface of second finger of other hand. All parts may be reached readily. In percussing lung apices, sometimes individual structural peculiarities of subjects make it desirable to strike the thumb instead of the second finger. When the fingers of the "pleximeter hand" are separated (e.g., a finger placed in each intercostal space) a large area may be percussed rapidly, and, as is often highly desirable, comparisons

and contrasts between the percussion tones are possible quickly, without moving the "pleximeter" about and while so doing, running the risk of losing previously elicited tones. This maneuver is employed very advantageously during chest percussion when it is desired to locate the borders of consolidation, fluid, atypical air collections, etc.

After dexterity and accuracy have been achieved by a few weeks practice with the method and when the fingers have lost their memories of the present, commonly-used percussion technic many interesting and useful variations in the application of the method described will suggest themselves.

Some of the advantages of the percussion technic here mentioned appear to be

- 1 Long continued work with avoid-

Further Observations on Primary Carcinoma of the Liver in Chinese

By G F STRONG, M D, and H H PITTS, M D, *Vancouver, B C*

IN a previous article¹ in 1930 we reported nine cases of primary carcinoma of the liver seen at the Vancouver General Hospital between 1920 to 1927, inclusive. Eight of these were Chinese and one a white man. We now add three additional cases seen in the four years, 1928 to 1931, of which two are Chinese and one white. This total of twelve cases of undoubted primary carcinoma of the liver in the twelve year period is large, and is an indication of the extreme frequency of this type of malignancy among these Chinese. Analysis of the incidence in the separated racial groups will show that as far as whites are concerned our findings are comparable to those reported elsewhere. When the incidence in Chinese is considered it is found to be very high, so high that it would seem wise to consider the matter further to ascertain if possible what factors account for this great frequency.

Primary carcinoma of the liver is one of the rarer forms of cancer. Counsellor and McIndoe² collected a series of 42,276 autopsies in which the incidence of this malignancy was only 0.14 per cent. The incidence in our series was 12 cases in 1967 autopsies or

0.61 per cent. This is so extremely high that it immediately raises the question as to the criteria used for making this diagnosis. It should be mentioned that during these twelve years we have seen other cases so diagnosed which have been rejected because the proof seemed inadequate. We have included only those cases in which a complete autopsy was performed and in which, furthermore, the microscopic sections showed a definite primary carcinoma of the liver of either the hepatoma or cholangioma type. An additional criterion was the presence of a definite cirrhosis. This was true in all but one of our cases as will be described in detail later. To further satisfy ourselves we submitted most of this material to Dr. Wm. Boyd, Professor of Pathology at the University of Manitoba, who was kind enough to review it and to have made the photomicrographs which illustrate this paper. We feel that there can be no doubt as to the diagnosis of these selected cases.

When the percentage incidence in the different racial groups is considered (table I), the enormous increased frequency in the Chinese is immediately evident. Again, if we there were 2 cases in 1828 autopsies or 0.109 per cent, which is slightly more than the incidence of this carcinoma

¹Presented at the San Francisco meeting of the American College of Physicians April 5, 1932.

TABLE I

Incidence of	Primary	Carcinoma	Liver
NUMBER	NUMBER OF	PERCENTAGE	
OF CASES	AUTOPSIES	INCIDENCE	
Total	12	1967	0.61
White	2	1828	0.109
Chinese	10	139	7.19
Counsellor and McIndoe ²		42276	0.14

incidence in Chinese with 10 cases in 139 autopsies, or 7.19 per cent, is extremely high

The Chinese resident in British Columbia come almost entirely from the province of Kwangtung in the south of China, most of them being Cantonese. In trying to discover what factors might be responsible for this tremendous incidence of primary carcinoma of the liver we had to secure what information we could from that part of China. Statistics from Central or Northern China are of little, if any, assistance because of the great difference in environmental factors. It is impossible to obtain accurate autopsy statistics from Kwangtung, but we were able to secure some information of value. Most of this was reported in our previous paper and needs only brief mention here. There can be no doubt that the incidence of chronic diseases of the liver, both cirrhosis and cancer, is greatly increased in Southern Asia and particularly in the south of China. One autopsy series showed more primary carcinoma of the liver than primary carcinoma of the stomach. It is also generally agreed that one, if not the main, cause for this increased incidence of chronic liver disease is the very great frequency of chronic intestinal disease including infestation with intestinal parasites. The commonest and probably most likely cause of chronic liver disease is the liver fluke,

Clonorchis sinensis, which is acquired by eating raw fish, a habit very common in this part of China. There are certain areas in Southern China where infestation with this liver fluke is so general as to approximate 100 per cent of the population. In such areas the incidence of primary carcinoma of the liver is known to be high. All of our Chinese cases showed a definite cirrhosis which we take to indicate that the liver had been subjected to long continued chronic irritation before the development of the malignant process. The pathogenesis would appear to be early and repeated, or long continued, infection with liver fluke with resulting chronic irritation leading to the development of a low grade hepatitis and cirrhosis. After years of this irritation some cases develop malignant degeneration. The nature of the irritant and whether mechanical or toxic or both is not clear. This is, however, another instance of the potency of chronic irritation in the production of cancer.

It is not to be inferred that all liver disease results from *Clonorchis* infection, for other parasites also occur and chronic bacterial infections of the intestinal tract are not unusual. The liver fluke is certainly the most common offender. Investigation has shown that the great majority (75 per cent in one series) of Chinese coming to British Columbia are infested with liver flukes. Ordinarily such infestation causes no symptoms and is not considered a cause for exclusion from the country.

Because of the growth of Vancouver and the failure of hospital facilities to keep pace with that growth, the number of Chinese patients admitted to the Vancouver General Hospital is gradu-

ally being reduced. Overcrowding of that institution, particularly during 1927-1930, has led to the gradual exclusion of the Chinese patient. A separate hospital for Orientals has also decreased the number of Chinese admitted to the General Hospital. Reference to table II shows the reduction in the

currence. It is regretted that the clinical details in some of these cases are so meager. In some instances the patient was moribund on admission and no history was obtainable. The last case is reported in more detail because it was one of the two in which the correct ante mortem diagnosis was made.

TABLE II
Comparison of Deaths and Autopsies Among Whites and Chinese

YEAR	TOTAL DEATHS	WHITE DEATHS	AUTOPSIES WHITE		CHINESE DEATHS	AUTOPSIES CHINESE	
			No	%		No	%
1920	688	641	113	17.6	47	19	40.4
1921	598	568	121	21.3	30	12	40.0
1922	654	598	126	21.0	56	19	33.9

Total Autopsies —			1967				

number of deaths and autopsies on Chinese. If this continues, as seems most likely, we will shortly see only an occasional Chinese at the Vancouver General Hospital. Table II shows also the increasing percentage of autopsies on whites. It is of interest that practically the same number of autopsies on whites was performed in the four year period, 1928-1931, as in the previous eight years and in each series there occurred one case of primary carcinoma of the liver in a white man.

The cases are reported briefly here-with in the order in which they appeared in our original article with the three recent cases in order of their oc-

ABSTRACT OF CASES

Case I Q. S. hospital no B76010 Chinese laborer, aged 45, was admitted Oct. 22, 1926 complaining of swelling of the abdomen and legs and progressive weakness. He had been in Canada 20 years. In January, 1926 he became weak and unable to work. In July his abdomen was larger and a tender lump appeared in right epigastrium. He lost 11 to 18 lbs. in weight.

Examination showed an emaciated, middle-aged Chinese with distention of the right chest. His abdomen was tender with fluid. After 210 cc. of ascitic fluid had been removed the patient's condition was not improved. The epigastrium was a little tender and the liver was enlarged. The liver was removed and weighed with the stomach and

tion. The spleen was not enlarged. There was considerable edema of legs and feet.

Laboratory observations Wassermann (blood), negative. Urine albumen, a trace, and occasional hyaline casts. N.P.N. 33 mgm. per 100 c.c. of blood. Red blood cells, 3,602,000, hemoglobin, 70%, white blood cells, 5,500. Gastro-intestinal x-ray, negative. Fluoroscopic examination showed the right side of diaphragm to be elevated to the level of the second rib, apparently due to an enlarged liver. Because of our previous observations of primary carcinoma of the liver in Chinese such a diagnosis was made in this case. He remained in hospital four months, until his death, Feb 13, 1927. The clinical course was that of a rapidly progressive hepatic cirrhosis.

Autopsy report. The body was that of an emaciated, middle aged Chinese, with abdomen distended with fluid. The right lung was firm in its lower half and seemed to be contiguous with the liver. The reason for this compression was seen to be due to an extremely large growth originating in the liver which had grown through the diaphragm on the right and produced an upward displacement of the lower lobe of lung but had not invaded the lung proper. On section it presented a somewhat lobulated grayish-white, firm, slightly bile-tinged, carcinomatous appearance. The right lobe of the liver was generally involved, the left less so. The portal system was markedly compressed and the gastro-intestinal tract intact throughout. The left lung was negative. The heart was removed without detaching it from the right lung, and a projection of the growth the size of a hen's egg was found in the right auricle. The peritoneal cavity was filled with chylous ascitic fluid. Further examination of the body revealed no other primary focus or other pathology. An anatomical diagnosis of primary carcinoma of the liver with extension through the right side of the diaphragm to the right pleural cavity and right auricle was made. Histological examination of the various sections from the liver confirmed this and showed an associated extensive cirrhosis.

Diagnosis. Primary carcinoma of liver (cholangioma type), with cirrhosis.

Case II. J. Y., hospital no A95277, Chinese laborer, aged 33, was admitted June 18, 1920. No history was obtainable. He presented marked edema of the feet, legs and abdomen. The liver was enlarged and nodular. The patient lived only one and one-half hours after admission.

Autopsy report. There was edema of the lower extremities. The peritoneal cavity showed ascites. The liver weighed 6,650 gm. There were grayish-white nodules of varying size, from 1 to 6 cm in diameter, almost all in the right lobe. The intervening liver tissue was grossly cirrhotic. Metastatic nodules were present in both lungs. No evidence of other primary growth was revealed on further examination.

Microscopic observations. In this tumor the cells were not as large as those seen in several of the other tumors of this series. They were slightly pleomorphic, and the nuclei were hyperchromatic, pyknotic and mitotic. The cells were arranged in solid, relatively small, aggregations with no attempt at acinar or duct formation, and in one area a definite tumor embolus was seen in a large vein. A well defined cirrhosis was present throughout.

Diagnosis. Primary carcinoma of the liver (hepatoma type), with cirrhosis.

Case III. Y. M., a Chinese laborer, aged 45, was admitted to the hospital on March 11, 1921. The past history revealed nothing significant. For fourteen months he had suffered from loss of weight and pain in the upper part of the abdomen, with occasional attacks of fever. The patient was emaciated, with definite ascites and edema of the feet and legs. The liver was enlarged. He died on April 4.

Autopsy report. There was marked edema of the lower extremities and cavity was filled with bloody fluid. The liver weighed 4,970 gm, with the right lobe almost completely replaced by large, grayish-white tumor masses, one, superficially placed, being extremely degenerated and hemorrhagic, apparently the source of the intraperitoneal hemorrhage. The left lobe also was studded with smaller nodules, many of which were bile stained, the intervening liver substance being cirrhotic. Metastatic nodules were

found in the lungs, omentum and brain. No other primary growth was found on further examination of the body.

Microscopic observations Sections through the tumor tissue showed it to consist of an aggregation of large, atypical, pleomorphic, hyperchromatic cells, many of which were extremely large with multinucleation and mitoses. In some areas the cells were arranged in fairly compact masses, in others more loosely arranged, but on the whole the stroma was sparse and fairly general degeneration was apparent throughout. Definite periportal cirrhosis was in evidence.

Diagnosis Primary carcinoma of the liver (hepatoma type), with cirrhosis.

Case IV G Y, hospital no B2907, Chinese laborer, aged 57, was admitted Jan 17, 1921. He presented swelling of the feet and abdomen, weakness and loss of weight for one month. Ascites and edema of the feet were present. He died on Jan 24.

Autopsy report Relatively little of note was found on external examination. There was no edema of the extremities or ascites. The peritoneal cavity was filled with clotted and fluid blood. The omentum was adherent apparently by recent adhesions to a mass in the inferior aspect of the right lobe of the liver in which a deep hemorrhagic split was present, evidently the source of the hemorrhage. The liver weighed 3,060 gm. It had been converted into a rather sclerotic, yellowish-white mass with relatively little normal liver tissue present, with areas of necrosis throughout. Finger-like processes of tumor tissue were found protruding into the inferior vena cava. No metastases were found in the lungs, and there was no evidence of other primary growth elsewhere in the body.

Microscopic observations The cells were large, fairly uniform, hyperchromatic and atypical, the nuclear material was especially dense but the cells generally showed none of the giant-like forms seen in many of the hepatoma types. They were arranged about definite, variously sized, ductlike spaces while in many areas definite tumor emboli were seen within vascular channels. Degenerative and inflammatory changes were in evidence with a definite but relatively fine cirrhosis throughout.

Diagnosis Primary carcinoma of the liver (cholangioma type), with cirrhosis.

Case V L H K, hospital no B21104, Chinese laborer, aged 47, was admitted June 24, 1922. No history was obtainable. He complained of ascites and edema of the legs. He died on June 25.

Autopsy report There was some edema of the lower extremities. The peritoneal cavity was filled with serosanguineous fluid. The liver weighed 2,400 gm and was markedly cirrhotic in appearance, with many smaller and larger grayish-white nodules scattered throughout, chiefly in the right lobe. In one area, a process of tumor tissue protruded into the right portal vein. Several grossly involved perigastric lymph glands were present. There was no evidence of further metastases or other primary growth on further examination.

Microscopic observations The cells were pleomorphic, generally pale staining and arranged in solid sheets surrounding spaces which were evidently vascular sinuses lined by elongated endothelial cells, apparently of the Kupffer type. In other areas, aggregations of dissimilar cells were seen which were of relatively enormous size, pale and with multinucleation into many bizarre formations. Dense fibrotic bands surrounded these areas while in the former areas definite but finer cirrhosis was evident.

Diagnosis Primary carcinoma of the liver (hepatoma type), with cirrhosis.

Case VI H C, hospital no B25404, Chinese laborer, aged 21, was admitted Nov 5, 1922. Six days before admission he noted anorexia, headache and increasing vomiting. He was in coma at the time of admission and died two days later. Ascites was present. The liver was palpable. There was no edema of the feet.

Autopsy report There was no edema or ascites. The liver weighed 1,050 gm. A single, large, grayish white mass of tumor tissue completely replaced the right lobe of the liver with a few smaller discrete nodules surrounding it. No metastases were seen. There was no other primary growth or evidence of further examination of the body.

Microscopic observations The tumor cells were uniform, size rather small, pale

tion. The spleen was not enlarged. There was considerable edema of legs and feet.

Laboratory observations. Wassermann (blood), negative. Urine albumen, a trace, and occasional hyaline casts. N.P.N. 33 mgm. per 100 cc of blood. Red blood cells, 3,602,000, hemoglobin, 70%, white blood cells, 5,500. Gastro-intestinal x-ray, negative. Fluoroscopic examination showed the right side of diaphragm to be elevated to the level of the second rib, apparently due to an enlarged liver. Because of our previous observations of primary carcinoma of the liver in Chinese such a diagnosis was made in this case. He remained in hospital four months, until his death, Feb 13, 1927. The clinical course was that of a rapidly progressive hepatic cirrhosis.

Autopsy report. The body was that of an emaciated, middle aged Chinese, with abdomen distended with fluid. The right lung was firm in its lower half and seemed to be contiguous with the liver. The reason for this compression was seen to be due to an extremely large growth originating in the liver which had grown through the diaphragm on the right and produced an upward displacement of the lower lobe of lung but had not invaded the lung proper. On section it presented a somewhat lobulated grayish-white, firm, slightly bile-tinged, carcinomatous appearance. The right lobe of the liver was generally involved, the left less so. The portal system was markedly compressed and the gastro-intestinal tract intact throughout. The left lung was negative. The heart was removed without detaching it from the right lung, and a projection of the growth the size of a hen's egg was found in the right auricle. The peritoneal cavity was filled with chylous ascitic fluid. Further examination of the body revealed no other primary focus or other pathology. They were slightly pleomorphic, and the nuclei were hyperchromatic, pyknotic and mitotic. The cells were arranged in solid, relatively small, aggregations with no attempt at acinar or duct formation, and in one area a definite tumor embolus was seen in a large vein. A well defined cirrhosis was present throughout.

Diagnosis. Primary carcinoma of the liver (hepatoma type), with cirrhosis.

Case III. Y. M., a Chinese laborer, aged 45, was admitted to the hospital on March 11, 1921. The past history revealed nothing significant. For fourteen months he had suffered from loss of weight and pain in the upper part of the abdomen, with occasional attacks of fever. The patient was emaciated, with definite ascites and edema of the feet and legs. The liver was enlarged. He died on April 4.

Autopsy report. There was marked edema of the lower extremities and cavity was filled with bloody fluid. The liver weighed 4,970 gm, with the right lobe almost completely replaced by large, grayish-white tumor masses, one, superficially placed, being extremely degenerated and hemorrhagic, apparently the source of the intraperitoneal hemorrhage. The left lobe also was studded with smaller nodules, many of which were bile stained, the intervening liver substance being cirrhotic. Metastatic nodules were

found in the lungs, omentum and brain. No other primary growth was found on further examination of the body.

Microscopic observations Sections through the tumor tissue showed it to consist of an aggregation of large, atypical, pleomorphic, hyperchromatic cells, many of which were extremely large with multinucleation and mitoses. In some areas the cells were arranged in fairly compact masses, in others more loosely arranged, but on the whole the stroma was sparse and fairly general degeneration was apparent throughout. Definite periportal cirrhosis was in evidence.

Diagnosis Primary carcinoma of the liver (hepatoma type), with cirrhosis.

Case IV G Y, hospital no B2907, Chinese laborer, aged 57, was admitted Jan 17, 1921. He presented swelling of the feet and abdomen, weakness and loss of weight for one month. Ascites and edema of the feet were present. He died on Jan 24.

Autopsy report Relatively little of note was found on external examination. There was no edema of the extremities or ascites. The peritoneal cavity was filled with clotted and fluid blood. The omentum was adherent apparently by recent adhesions to a mass in the inferior aspect of the right lobe of the liver in which a deep hemorrhagic split was present, evidently the source of the hemorrhage. The liver weighed 3,060 gm. It had been converted into a rather sclerotic, yellowish-white mass with relatively little normal liver tissue present, with areas of necrosis throughout. Finger-like processes of tumor tissue were found protruding into the inferior vena cava. No metastases were found in the lungs, and there was no evidence of other primary growth elsewhere in the body.

Microscopic observations The cells were large, fairly uniform, hyperchromatic and atypical, the nuclear material was especially dense but the cells generally showed none of the giant-like forms seen in many of the hepatoma types. They were arranged about definite, variously sized, ductlike spaces while in many areas definite tumor emboli were seen within vascular channels. Degenerative and inflammatory changes were in evidence with a definite but relatively fine cirrhosis throughout.

Diagnosis Primary carcinoma of the liver (cholangioma type), with cirrhosis.

Case V L H K, hospital no B21104, Chinese laborer, aged 47, was admitted June 24, 1922. No history was obtainable. He complained of ascites and edema of the legs. He died on June 25.

Autopsy report There was some edema of the lower extremities. The peritoneal cavity was filled with serosanguineous fluid. The liver weighed 2,400 gm and was markedly cirrhotic in appearance, with many smaller and larger grayish-white nodules scattered throughout, chiefly in the right lobe. In one area, a process of tumor tissue protruded into the right portal vein. Several grossly involved perigastric lymph glands were present. There was no evidence of further metastases or other primary growth on further examination.

Microscopic observations The cells were pleomorphic, generally pale staining and arranged in solid sheets surrounding spaces which were evidently vascular sinuses lined by elongated endothelial cells, apparently of the Kupffer type. In other areas, aggregations of dissimilar cells were seen which were of relatively enormous size, pale and with multinucleation into many bizarre formations. Dense fibrotic bands surrounded these areas while in the former areas definite but finer cirrhosis was evident.

Diagnosis Primary carcinoma of the liver (hepatoma type), with cirrhosis.

Case VI H C, hospital no B25496, a Chinese laborer, aged 21, was admitted Nov 5, 1922. Six days before admission he noted anorexia, headache and increasing vomiting. He was in coma at the time of admission and died two days later. Ascites was present, the liver was palpable. There was no edema of the feet.

Autopsy report There was no edema or ascites. The liver weighed 1,950 gm. A single, large, grayish-white mass almost completely replaced the right lobe of the liver with a few smaller discrete nodules surrounding it. No metastases were found and no other primary growth was revealed on further examination of the body.

Microscopic observations The tumor cells were uniform in size, rather small and for

FIG 1 (Case VI) Section of tumor, X 125 Well marked but aborted attempts at bile-duct formation are seen, the lining cells are very atypical and hyperchromatic, while frequent intercommunications between neighboring ducts are apparent

FIG 2 (Case III) Section of tumor, X 200 Numerous giant cell formations which are frequent chiefly in the hepatoma type of carcinoma of the liver

the most part surrounded gland or ductlike spaces, many of which were very elongated. Mitotic figures were numerous, but none of the very large cells were seen. A moderate amount of coarse cirrhosis was present throughout.

Diagnosis Primary carcinoma of the liver (cholangioma type), with cirrhosis.

Case VII L. L. F., hospital no. B31984, Chinese laborer, aged 53, was admitted May 15, 1923. Extreme emaciation was evident. There was no edema of the extremities. The liver was slightly enlarged. There was no ascites. The patient died on May 26.

Autopsy report External examination gave negative results. There was no ascites or edema. The liver weighed 2,000 gm and was studded with grayish-white nodules from 2 mm to 2 cm in diameter throughout both lobes. A few smaller, similar nodules were present in the spleen. Several metastatic nodules were found in three of the left ribs. No other primary growth was found on examination of the remainder of the body.

Microscopic observations Throughout these sections many cords and columns of pleomorphic cells of liver type were seen. Many of them were extremely large, with correspondingly large nuclei in which mitotic figures were frequent. Interspersed throughout were well defined bands of fibrous tissue of cirrhotic type in which fairly numerous but well developed biliary ducts were present.

Diagnosis Primary carcinoma of the liver (hepatoma type), with cirrhosis.

Case VIII McM., hospital no. B73930, a white laborer, aged 76 years, was admitted July 12, 1926. He had had weakness for two years. Edema of the feet, legs and abdomen was getting gradually worse. He was comatose at the time of admission and died on July 13.

Autopsy report There was edema of the lower extremities. Serosanguineous fluid was present in the peritoneal cavity and in both pleural cavities. The liver weighed 2,500 gm and was studded throughout with many grayish-white, bile stained nodules, while a larger superficial mass on the superior surface of the right lobe was adherent to the hepatic flexure of the colon but did not

extend into the lumen. Metastatic nodules were also present in the lungs. No other primary growth was found on further examination of the body.

Microscopic observations The picture presented in the sections from this tumor was practically identical with that seen in case VII, with the exception of an almost complete absence of cirrhotic changes. This would seem to be of interest owing to the fact that it is from one of the two white men in our series and is the only patient showing *no cirrhosis*.

Diagnosis Primary carcinoma of the liver (hepatoma type).

Case IX L. L., no hospital number, a Chinese laborer, aged 35, admitted to the emergency ward in an unconscious state on Sept. 5, 1927, and died within a few minutes after admission.

Autopsy record The body was that of a well-developed and nourished Chinese man. Nothing remarkable was apparent on external examination. The peritoneal cavity was completely filled with clotted and fluid blood, the source of which was found at the margin of the lower portion of the right lobe of the liver where a large degenerated carcinomatous mass, 8 by 6 cm., had eroded a large blood vessel, the thrombosed end of which was apparent. The liver was small, weighing only 1,090 gm. It was markedly cirrhotic. In the right lobe many grayish-white nodules, varying in size from that of a filbert to that previously noted, were seen, all more or less degenerated in appearance. The left lobe was free from nodules. A large tumor embolus was present in the first portion of the inferior vena cava. No gross metastases were found, and further examination of the body revealed no other primary growth.

Microscopic observations Sections through the liver showed the presence of many aggregations of atypical liver cells, some of which appeared to be from eight to ten times the size of the normal cells, irregular in shape, with large, single or multiple hyperchromatic nuclei frequently showing mitosis. No attempt at acinar or duct formation was apparent although in a few areas the cells were arranged in solid cylindric forma-

tions frequently showing considerable central degeneration. Extensive cirrhosis was present throughout with dense bands of fibrous tissue surrounding masses of these atypical cells. No tumor emboli were evident in the sections.

Diagnosis. Primary carcinoma of the liver (hepatoma type), with cirrhosis.

Case X S. H., coroner's autopsy, no history available. The body was that of a Chinese laborer, aged about 45, who had died Dec. 16, 1928. Autopsy showed hemorrhage into the gastro-intestinal tract. No evidence of cancer of stomach or intestines was found. The liver showed extensive cirrhosis and carcinomatous nodules. Histologically, these were carcinoma of the hepatoma type. An extensive cirrhosis was present.

Diagnosis. Primary carcinoma of liver (hepatoma type), with cirrhosis.

Case XI S. G. P., hospital no. C37523, a Chinese laborer, aged 44, was admitted Sept. 14, 1930, and died Sept. 26, 1930. His illness began one month previous to admission with indefinite pain in the right upper quadrant, sometimes followed by vomiting. Loss of weight (exact amount unknown), loss of appetite, acholic stools and icteroid tinge to conjunctivae were noted. Urine had been dark.

Physical examination. The patient was very emaciated, deeply jaundiced. The abdomen was not distended but tender over the right side. There was a nodular tender enlargement of the liver to below the level of umbilicus. X-ray examination of the gastro-intestinal tract was negative, and the Wassermann reaction was negative.

Autopsy report. The body was markedly jaundiced, emaciated, abdomen distended, right lower extremity edematous. There was a nodular mass in the right hypochondrium. Old fibrous pleurisy, bilateral, with an old tuberculous focus in apex of left upper lobe was found. There were 1½ pints of serosanguinous fluid in the abdominal cavity. The liver weighed 3,860 grms and was markedly nodular and greenish-yellow in color. On section, four large degenerated masses, varying from a navel orange to a medium sized grapefruit were seen, chiefly in the left lobe. Scattered throughout the re-

maining liver tissue were innumerable nodules varying from a bean to a walnut in size. These larger masses had varied colors: some cream-colored, others more deeply yellow and still others showing very extensive hemorrhagic extravasation. An advanced degree of cirrhosis was present in the intervening liver tissue. No evidence of any other neoplastic process was found and no metastases. A diagnosis of primary carcinoma of the liver was made. Histologically this proved to be of the hepatoma type and there was extensive cirrhosis.

Diagnosis. Primary carcinoma of liver (hepatoma type), with cirrhosis.

Case XII W. J., hospital no. C44523, English gardener, aged 57, was admitted March 11, 1931, and died May 4, 1931.

Complaints. Patient had not been as well as usual, with drenching night sweats. There were many bad teeth which he wished extracted.

History. This man was born in England in 1874, lived from 1892 to 1911 in India, came to Canada in the latter part of 1911, was in the Great War for four and a half years, discharged, A-1, no pension. Patient states that he has never been in bed until last year, when he was admitted because of carbuncle on his back. This was incised and patient got along very well. While in India the patient had malaria on several occasions which cleared up with the administration of quinine. He had also had some dysentery. He was treated early and with satisfactory results. Patient had a Neisserian infection while living in India but denied lues.

Present illness. This patient reported about one week ago requesting that he have complete extraction of all his infected teeth. Prior to having this done a general examination was made and on questioning he stated that for the past three weeks he had been having very drenching night sweats and has had to change as often as ten times a night. About Christmas time he had a sharp pain in his right abdomen which doubled him up and at that time he reported to the Emergency Ward and was given some Sippy powders and placed on modified Sippy diet. He states that the pain cleared up shortly and he has not been bothered since. Bowels are

regular when at his work which gives him considerable exercise, but when lying in bed he requires aperients each night

Examination The patient was found to be a rather short man, slightly stooped and in poor physical condition. His weight has dropped 20 lbs in the last month. Teeth were in very bad shape, x-ray showed several infected roots. On the left side of neck at the angle of jaw there was a small hard gland, also a few very small glands in the posterior triangle, possibly from the infected teeth. Lungs and heart were normal. Blood pressure was 135/78. A tumor could be seen about midway between the costal margin and the pubes which moved freely on respiration and on palpation there could be felt a very definite, firm mass. This appeared to be the lower margin of the liver. Spleen was also palpable. Rectal examination was negative. Pupils and reflexes were normal.

Laboratory findings Gastro-intestinal x-ray examination showed no evidence of an intrinsic organic lesion. However, the hepatic flexure, ascending colon and proximal half of the descending colon were displaced downwards and inwards, apparently by a mass in the right hypochondrium. Blood Kahn reaction was negative. Red blood cells, 5,216,000, hemoglobin, 94%, white blood cells, 11,100, polymorphonuclears, 78%. Urinalysis essentially negative. Van den Bergh normal delayed reaction, normal quantitative estimation. A provisional diagnosis of primary carcinoma of the liver was made and on March 21, 1931, an exploratory laparotomy was performed, confirming this diagnosis. The patient became progressively weaker and emaciated, with quite frequent drenching night sweats, and expired May 4, 1931.

Autopsy findings The body was that of a fairly well developed but extremely emaciated white male, 57 years of age. There was little of note on external examination beyond the presence of an old long right rectus incision, healed, and a nodular mass in the right upper quadrant of the abdomen. The dome of the diaphragm on the right reached to the fourth rib. Pleural cavities were free, however, and the right lung was emphysematous throughout and showed an occasional

small plaque-like half-bean-sized greyish-pink subcapsular nodule, these nodules were also seen in the left lung. The posterior half of the left lower lobe was edematous, congested, and showed scattered bronchopneumonic areas. The heart was of normal size and showed relatively little of note grossly. The liver extended 9 cms below the right costal border, 2 cms below the left costal border, and 3 cms below the ensiform in the midline. The upper limit of its right lobe was, as before stated, at the level of the fourth rib. The liver weighed 3,860 grms. It was markedly nodular, studded with innumerable greyish-white, relatively soft, somewhat rubbery nodules, varying from a filbert to a grapefruit in size. The right lobe was chiefly involved and its lower border, posteriorly, was at the crest of the ilium. It was markedly adherent to the cecum and hepatic flexure which were pushed anteriorly and medially by the growth. The gall bladder was small but grossly intact. On section these nodules were seen to be very extensively degenerated, especially the larger ones, and presented varying colors—some were yellowish, others more greyish-white, and still others showed extensive hemorrhagic extravasation. The smaller ones showed an outer rim of relatively well preserved tissue with central areas of degeneration. A few perigastric and pre-aortic involved glands were present. The gastro-intestinal tract was negative throughout. The pancreas, though adherent to the undersurface of the growth, showed no evidence of neoplasm. Spleen, kidneys and adrenals were also quite innocent of any neoplastic process and showed relatively a normal gross appearance. The bladder and prostate were also negative. The brain was examined and no evidence of pathology found. This was evidently a primary carcinoma of the liver with metastases to regional lymph glands and lungs, and terminal bronchopneumonia in the left lower lobe.

Microscopic findings A large number of sections were taken through the various portions of the liver and through the small plaque-like nodules in the lungs and involved regional glands. They showed a neoplastic process, characterized by very large more or

less spherical, deeply-staining cells of atypical epithelial form. Mitotic figures were frequent but no tendency toward giant cell formation was evident. The cells were frequently arranged in columns with spaces between. A very sparse fine trabecular stroma was present and where the liver tissue was incorporated there was a definite but relatively slight cirrhosis. The spaces mentioned above were evidently aborted attempts at duct formation. Extensive fatty infiltration and considerable hemorrhagic extravasation was also present. The sections through the glands and nodules in the lungs showed a process similar to the above.

Diagnosis Primary carcinoma of the liver (cholangioma type), with cirrhosis. Metastases to lungs and regional lymph glands.

COMMENT

Sex and Age All twelve cases occurred in males. We see a much smaller number of Chinese women in proportion to men than is true in whites. This is not sufficient to explain the great frequency of primary carcinoma of liver in males. Our impression is that some additional environmental factor must play a part in the causation of this condition. The average age was 46.5 with extremes of 21 to 76 years.

TABLE III
Age Incidence

DECADE	CHINESE	WHITE
21 to 30	1	0
31 to 40	2	0
41 to 50	5	0
51 to 60	2	1
61 to 70	0	0
71 to 80	0	1
	<hr/> 10	<hr/> 2

It is interesting that 5 of the 10 Chinese cases occurred in the fifth decade.

Symptoms There are no symptoms characteristic of primary carcinoma of the liver. The patients usually present the clinical picture of a rapidly progressive cirrhosis of the liver with un-

usually speedy emaciation. Edema of the extremities commonly occurs and ascites is usual. Jaundice occurs in some cases but is not constant. The high fixed liver may be a suggestive factor in the diagnosis. This was noted in a number of our cases. It was especially well shown in case I in which a radiograph of the chest showed the right diaphragm up to the second rib. The liver was fixed and did not descend with inspiration or changes in posture.

Antemortem diagnosis of primary carcinoma of liver was made in two cases, I and XII in this series. In case I this was made entirely on clinical evidence and on the negative laboratory findings. The high fixed liver was a noticeable feature here. In case XII the antemortem diagnosis was confirmed by an exploratory laparotomy and biopsy.

PATHOLOGY

Primary carcinoma of the liver may be divided into two types on the basis of the cellular pathologic changes: (1) hepatoma, a true liver cell tumor, and (2) cholangioma, a bile duct tumor.

In this series there were eight hepatomas and four cholangiomas.

The relation of cirrhosis to primary carcinoma of the liver is definitely established. Some observers go so far as to question the diagnosis of a primary carcinoma of the liver in the absence of a definite cirrhosis. The cirrhosis may be either portal or biliary and is probably a precursor of the carcinoma. In cirrhosis, a degeneration of the liver cells and bile ducts occurs followed by some evidence of regeneration or attempts at regeneration which may re-

sult in the disorderly growth which characterizes these carcinomas Eggel⁴ found cirrhosis in 85 per cent of hepatomas and 50 per cent of cholangiomas. In our series, cirrhosis was present in all four of the cholangiomas and in seven of the eight hepatomas, the exception being in one of the white patients in the series. The microscopic sections in this case were so definitely those of a true hepatoma that we have no hesitation in including it in this series in spite of the absence of the usual cirrhosis.

Metastasis appears to occur entirely by the blood stream. The hepatomas invade the capillaries and gross tumor emboli are frequently seen in these cases in portal vein radicles and in the inferior vena cava. The cholangiomas are said to metastasize earlier and more frequently than the hepatomas. In this series, however, metastases were more frequent among the hepatomas, occurring in five of the eight cases and being found in only two of the four cholangiomas. The lungs were involved in five cases, the ribs and spleen in one case, the mesenteric and perigastric glands in two, and the brain in one.

While nothing has been added to our knowledge of primary carcinoma of the liver by this contribution it seemed worthy of record (1) because of the rather large number of cases of a comparatively rare condition, and (2) because of the high incidence in the Chinese. This increased incidence in the Chinese in our series is, we believe, a result of the fact that these immigrants come from Kwangtung, a province in China where chronic disease of the liver and primary carcinoma of the liver are of more frequent occurrence,

than in other parts of China. Infection with *Clonorchis sinensis* may have been the exciting factor in the production of some of these primary carcinomas while others may have resulted from chronic irritation of the liver due to other causes (hepatitis with resulting cirrhosis). While the actual parasites were not found in any of our cases, the infection with *Clonorchis* is after all only the exciting factor, the parasites setting up a chronic irritation resulting in a cirrhosis and in some cases in primary carcinoma.

In an autopsy on a Japanese male, aged 46, we found an extensive involvement of the liver with *Clonorchis sinensis* which had converted it into a more or less polycystic, markedly degenerated structure, these cyst formations being dilated biliary channels. Histologically, definite evidence of cirrhosis, bile duct and slight liver cell regeneration was apparent. This seems of interest in the possible correlation of cirrhosis of the liver with primary carcinoma, for, as Maxwell states from personal knowledge, primary carcinoma of the liver is common in certain limited areas in China where *Clonorchis* infection is common.

In the past three months we have found a coincident *Clonorchis* infection in a Chinese woman dying of a miliary tuberculosis and in a Chinese male dying of massive hemorrhage from gastric ulcer. These had produced no gross pathologic change in the liver and on histological examination showed only a chronic cholangitis. It seems probable that had these patients lived, a more definite cirrhotic process might have been established.

The liver in one of our white cases

showed no cirrhosis but in the other, case XII, there was a very slight degree. This is of interest as this man had lived in India on a tea plantation for 20 years and gave a history of malaria and, apparently, dysentery, and there is a likelihood of his having had some parasitic infection while there.

CONCLUSION

1 A series of twelve cases of primary carcinoma of the liver is presented. Ten of these are in Chinese and two in whites. These were observed at the Vancouver General Hospital in the twelve years, 1920 to 1931, inclusive.

2 The incidence of the series as a whole was 12 cases in 1967 autopsies, or 0.61 per cent. The incidence in whites was: 2 cases in 1828 autopsies, or 0.109 per cent. The incidence in Chinese was 10 cases in 139 autopsies, or 7.19 per cent.

3 The Chinese came entirely from the province of Kwangtung in the

south of China. Investigations have shown that in that area as high as 100 per cent of the population are infested with intestinal parasites. The commonest is the liver fluke, *Clonorchis sinensis*. All of these cases showed a cirrhosis suggesting previous chronic liver irritation.

The high incidence of primary carcinoma of the liver in these Chinese may, we believe, be a result of the frequent infestation with intestinal parasites.

5 Eight of the twelve cases were hepatomas or liver cell carcinomas. Four were cholangiomas or bile duct cell carcinomas.

Some Recent Observations Regarding the Nature of Epilepsy

By IRVINE McQUARRIE, M D, *Minneapolis, Minn*

INTRODUCTION

A SURVEY of the literature on the subject reveals the fact that there has been a notable revival of interest in the problem of epilepsy during the past few years. Although the annals of medical history are replete with references to this bizarre convulsive disorder, there have been but two short periods before the present in which measurable progress toward solution of its problems has been made. The first of these was that in which the illustrious Greek physician, Hippocrates (460-347 B C)¹ succeeded in dissipating the cloud of superstition that had previously enshrouded the disease and laid the foundation for our present conception regarding it. The second covered a span of approximately thirty years (1855-1885), during which Laycock² introduced bromide therapy and Kussmaul and Tenner,³ Jackson,⁴ Gowers⁵ and others made a vigorous attack upon the problem of pathogenesis using both clinical and experimental methods.

From the Department of Pediatrics of the University of Minnesota, Minneapolis, Minnesota

Presented at the San Francisco Meeting of the American College of Physicians, April 6, 1932

Of special interest to us here is the fact that these early investigators expressed certain views regarding the nature of the disease which are similar to those held by leading neuropathologists today.^{6,7} In his plea for recognition of the fact that epilepsy is not a "sacred" disease but, like any other disorder of the body, has a natural cause, Hippocrates finally concluded that "whoever is acquainted with such a change in men and can render a man humid and dry, hot and cold by regimen could also cure this disease." Regarding the relative importance of various causative factors Kussmaul and Tenner (1859) made the following statement: "Every physician of the present day who is at all judicious will relinquish the hope cherished with childlike confidence by certain schools and times that pathological anatomy is destined to give an explanation of the nature and seat of epilepsy, and he will only expect that result from the progress of the experimental physiology of nerves." Gowers held a similar opinion, stating that, "It is a disease of tissue, not of structure." He was convinced that final solution of the problem must await further advances in brain cell physiology.

Among the contributions made during the present period have been the

following (1) The introduction of phenylethylbarbituric acid as a specific remedial agent; (2) the observation that marked symptomatic improvement results from fasting⁹ or from the use of a ketogenic diet,^{10,11} and the discovery that certain factors, such as the state of oxygenation of the blood,⁶ the acid-base equilibrium^{12,13,6,11} and the water balance of the body^{15,16} may greatly influence the occurrence of seizures. In their recent monograph on the subject Lennox and Cobb⁶ summarize the present status of the problem as follows "The physiological changes which we have mentioned (anoxemia, alkalosis and edema) are themselves only contributory factors. They tend to induce seizures by increasing the irritability of nervous tissues, producing an effect which is not specific for epilepsy. Furthermore, the physiological changes mentioned will produce seizures only in those who are subject to seizures. Therefore, the question yet remains, why, under a given stimulus, one person should have a seizure and another not. . . Though this variability is presumably related to the subtle chemistry of the brain cell, its elucidation is for the future. As we have emphasized above, there is no constant anatomical lesion in epilepsy, and only a minority of all patients with extensive cerebral pathology have fits. We are forced then to postulate some unknown constitutional element. This abnormal 'convulsive capacity' is presumably present in some degree in each person with epilepsy."

The purpose of the present paper is to review some of the data from several of our recent studies, which were undertaken primarily with the hope of

obtaining information regarding the basic nature of the elusive functional pathology ("nervous instability") upon which this "abnormal convulsive capacity" is dependent. Our experimental approach to the problem has been that of attempting to elucidate the mechanisms by which epileptic convulsions are either induced or prevented from occurring by certain changes in regimen. The particular studies presented here concern the relationship of water and mineral metabolism to the occurrence of seizures. While evidence obtained by this indirect method must of necessity be incomplete and more or less presumptive in character, it is obvious that any data whatsoever, which point to a disturbance in brain cell physiology, may be important for the ultimate solution of the problem.

RESULTS

Examples of data from two different series of clinical experiments are presented in detail on the accompanying graphic charts which are largely self-explanatory. They have been selected from a more extensive study on the water and mineral metabolism^{17,18} to illustrate several points of difference between the reaction of the epileptic and that of the normal subject under given conditions.

These conditions and the methods of procedure used were essentially as follows. Each experimental subject was kept in a small metabolism ward in company with another patient under the constant supervision of a well-trained special nurse. He was kept in bed under light covers continuously except for short periods when allowed up to use the bed-side commode and to be

weighed The room temperature was kept between 20° and 24°C and the relative humidity between 40 and 66 per cent so that there was no sensible sweating. Each day was divided into four six-hour periods in each of which the diet, water intake and medication were the same. At the end of each six-hour period the bladder was completely emptied into a weighed container, after which the net body weight was determined on an accurate scale sensitive to five grams. The food, water and medication for the next period were then given. The diet for the first patient (chart I), which was uniform throughout the study, consisted of distilled water, cane sugar, egg yolk, egg white, fresh 40 per cent cream, clear lemon juice and whole-milk powder—substances of comparatively constant composition which lend themselves to accurate analyses. In the second experiment (chart II), heavy cream and cane

sugar alone were given because it was desired in this instance to have a still lower mineral intake. The complete water balance was measured according to the method described by Newburg and Johnston¹⁹.

The experiments shown on chart I illustrate the effect of induced changes in the state of hydration of the body upon the mineral exchange and the occurrence of convulsive seizures in an epileptic girl fourteen years of age. This particular patient was selected for the study because of the great severity of her epilepsy (2 to 12 convulsions daily when not under treatment) and because she had previously been found to be amenable to luminal therapy and was extremely sensitive to alterations in her water balance. She was given a maintenance diet with sufficient water to satisfy her thirst and her physiological requirements under ordinary conditions, as determined by a three-day pre-

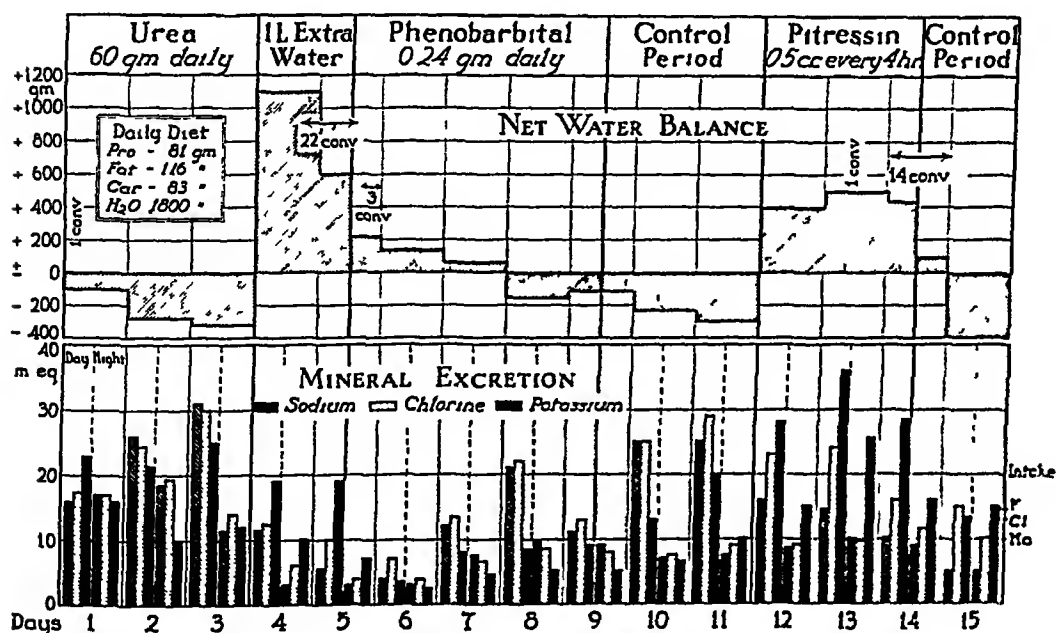

CHART I Relationship of water and mineral balances to the occurrence of convulsions under various conditions

liminary period, not included in the chart. The single variable factor for each distinct period is indicated at the top of the chart.

The close relationship between the water balance of the body and the occurrence of seizures was the most striking observation of this study. It is obvious that sudden storage of water was followed within from 18 to 36 hours by numerous *grand mal* attacks, whereas a negative balance from any cause was followed fairly promptly by their cessation. In respect to the mineral balance, the most important results were those pertaining to the excretion of potassium and sodium. The contrast between the non-convulsive and the convulsive periods, as regards the ratio of urinary K to urinary Na was striking. In all but the last period Na predominated during periods of negative water balance with freedom from seizures, whereas the excretion of K greatly exceeded that of Na during the convulsive periods. The ratio

$$\frac{\text{m eq K}}{\text{m eq Na}}$$

for each of the experimental periods was as follows: Urea period, 0.8; first water storage period, 2.5; phenobarbital period, 0.6; control period, 0.7; and pitressin period, 2.3. From the viewpoint of the pathogenesis of seizures these facts appear to us to be of considerable significance. When the large negative balance of K for the water storage periods was first recognized, it was casually looked upon as being merely secondary to the convulsions, that is, it was interpreted as representing nothing more than an attempt on the part of the tissues to furnish base

for neutralization of the H_2CO_3 and lactic acid accumulating in the body fluids during the seizures. The objection to this assumption, however, is the fact that the increase in K output manifested itself from 12 to 36 hours before the first convulsion of each series, at a time when water was being stored. This phenomenon was particularly striking during the pitressin antidiuresis period where it preceded the first convulsion by more than 36 hours.

Since in the human subject most of the K of the body is held within, and most of the Na outside, of the cells, as determined by the semipermeability of the cell membranes, it appears clear to us that the preponderance of Na and Cl in the periods of diuresis indicates removal of extracellular fluid; whereas, excessive excretion of K, as during the pitressin period, indicates a "leakage" of this element from within the body cells. This response to pituitary antidiuresis has not been seen in normal subjects nor in mildly epileptic patients in whom the procedure has not been pushed to the point of inducing seizures. In fact, normal subjects taking the diet given here show a predominance of Na and Cl excretion during pitressin antidiuresis. The amount of K in the pituitary extract is far too small to be a significant factor in the increased K output. It is interesting that K and Cl instead of Na and Cl predominated in the extra water eliminated in the post-pitressin period. This may be interpreted as indicating that stored extracellular water contained a considerable amount of K which had diffused into it from the cells during the pitressin period or that some of the water retained had been stored within

the cells and had carried K with it as it was expelled from them following the disappearance of the pitressin effect

The water and mineral exchanges during the period of intensive phenobarbital therapy were of special interest. The body weight, which had risen very rapidly during the preceding period of forced water drinking continued to increase slightly during the first three days with storage of small amounts of the various minerals. At the end of the second day the patient showed fairly marked puffiness of the face and definite pitting edema over the legs but with normal urine findings and no signs of myocardial insufficiency. This disappeared following the occurrence of a spontaneous diuresis, which began on the third day and reached its height during the post-phenobarbital

control period. The appearance of this subcutaneous edema, which cannot be adequately explained by the comparatively small magnitude of the positive water and mineral balances on these two days, suggests the possibility of a translocation of water from the intra- to the extracellular position.

Observations similar to the foregoing on the relationship of water storage to the occurrence of *grand mal* seizures in severely epileptic patients suggested the type of experiment represented on chart II. It was assumed that a more or less crucial test of the fundamental importance of this relationship in the disease would be the response of mildly epileptic patients to forced water drinking and simultaneous pituitary antidiuresis during their free intervals between regular attacks. Experiments

CHART II Effect of sustained pituitary antidiuresis on epileptic and non-epileptic subjects

undertaken with this in mind demonstrated that it is possible in a high percentage of cases to induce typical *grand mal* seizures (and very occasionally *petit mal*) by this procedure. Non-epileptic subjects of a similar age group have failed to have seizures of any kind when treated in the same or an even more rigorous manner. The results thus far suggest that the test is more or less specific in bringing out at least one characteristic weakness in the physiological adjustment of the epileptic patient, even when this is latent.

The data presented in chart II are typical in showing the contrast between the response of the non-epileptic and that of the epileptic subject to sustained pituitary antidiuresis. When both were placed on extremely low mineral diets and were given the amounts of water indicated and at the same time sufficient pitressin subcutaneously to prevent water diuresis, the mild epileptic had a typical seizure at the end of thirty hours and after a gain of only 1.5 kilograms, or 3 per cent, in body weight, whereas the non-epileptic had no convulsive reaction in spite of a gain of 2.5 kilograms, or more than 5 per cent, in body weight. The latter experienced much more abdominal discomfort, nausea and malaise before her test was completed than did the epileptic patient, which indicates that the control was sufficiently rigid.

Following the recovery of his water balance after the first test, the epileptic patient was again subjected to the procedure but this time with just sufficient NaCl added to the diet to prevent dilution of the extracellular body fluid by the retained water. As shown on the chart the effect of the latter mea-

sure was apparently to prevent the occurrence of a seizure even though the test was continued over 48 hours and 2.5 kilograms of water was retained as against 1.5 kilograms in the previous test. Several days later repetition of the procedure without addition of the salt was once more followed by a typical *grand mal* attack at the end of 18 hours. The resemblance between the reaction of the non-epileptic subject during the regular test and that of the epileptic, when extra NaCl was given, was striking to the last detail, except for the fact that the latter subject finally vomited after the procedure had been carried well beyond the point usually necessary for induction of seizures.

DISCUSSION

Although the data presented here are in themselves clear-cut, their interpretation in respect to the mechanism of the convulsive seizure must of necessity be highly tentative because the evidence is incomplete and is more or less inferential in character. Nevertheless, with these limitations definitely in mind, it is interesting to conjecture regarding the possible sequence of events which appear to lead up to the convulsion under the conditions of our experiments.

If we assume that epilepsy is a disorder of the nervous system in which there is an inherent disturbance in brain cell physiology, what particular function of the cell may be deficient? Having practically ruled out increased intracranial pressure and the vasopressor action of the pituitary extract as primary factors in the causation of seizures in the antidiuresis experiments,¹⁷ we believe that such data as we have

here may indicate an inherent weakness in the mechanism for controlling the semipermeability of the brain cell membranes. When the subject, who has been on a low mineral diet for a number of days, is forced by sustained antidiuresis to retain a volume of distilled water equal to from 3 to 6 per cent of his original body weight, a significant decrease in the total osmolar concentration of the electrolytes in his extracellular body fluids is found to occur. Under these conditions there is undoubtedly a strong tendency for an excess of water to enter the fixed cells of the brain and other organs and for intracellular elements to diffuse outward because of the lowered osmotic pressure of the fluid outside of the cell.

From the data presented, it appears that the normal subject can temporarily withstand the strain of this rather drastic modification of the extracellular fluid, whereas the epileptic's margin of protection is much narrower. We have pictured the situation tentatively somewhat as follows. The chemical structure of the brain cell membrane may be deficient or the cell colloids as a whole may be abnormal in their constitution or in their mutual relationships. Variability in clinical severity might well be determined then by the type and degree of abnormality present. In the case of the severely epileptic patient, (chart I) not only sustained pituitary antidiuresis, but the mere drinking of extra water following a period of dehydration resulted in the occurrence of many seizures. The mechanism here is probably the same as in the mild case (chart II) in which a convulsion was induced, namely, that extra water enters the cells and K diffuses from them

at the same time because of functional inefficiency in the cell membranes. It is conceivable that the resulting disturbance in the equilibrium between the various electrolytes and the imbibition of extra water by the cell colloids would account for the wide-spread irritability of the brain cells. The assumed imbibition of water by the brain cells with simultaneous loss of K has its analogy in the experimental observation of MacDonald,²⁰ that nerve tissue in Ringer's solution swells and loses K by diffusion at a point of stimulation or injury. It is known from the work of Syz²¹ and others that any form of excitation or injury increases cell membrane permeability. Most factors which increase cell membrane permeability probably increase excitability also.

Whether or not a disturbance in membrane activity, such as that postulated here for the purpose of discussion, would be more likely to depend upon a defect in the chemical structure of the brain cells or upon extrinsic nervous or hormonal factors cannot be said from the data now available. We have some evidence of a disturbance in the ratio of lecithin to cholesterol in the blood plasma in relationship to seizures.²² This may indicate an abnormal state of equilibrium between these physiologically antagonistic substances in the brain tissue, which is characteristically rich in them. While there was found no constant relationship between the occurrence of seizures and the absolute level of either cholesterol or lecithin, the ratio of the latter to the former was found repeatedly to be highest at or very near the time of a convulsion and lowest at the time most remote from one, when samples were taken

serially on an individual patient. In the light of the fact that lecithin and cholesterol are considered to play a major rôle in the regulation of cell membrane permeability,²³ these data tend to support the idea of defective cell structure. Comparative brain analyses are at present being made for further testing this possibility. There are facts, on the other hand, which indirectly suggest the alternative explanation of a disturbance in the extrinsic nervous or hormonal factors governing permeability. Further investigation in this field is urgently needed.

In favor of the view that the characteristic convulsive tendency of the epileptic is dependent upon an inherent defect in the mechanism for controlling this important cell function, is the circumstance that various factors (narcosis, sedation, etc.), which favor cessation of seizures, are known to decrease permeability, while those which favor their occurrence (alkalosis, anoxemia, injury, stimulation) are known to increase it. On the basis of general considerations such as the latter, Georgi²⁴ has already elaborated a theory of increased cell membrane permeability in this disease. While our evidence is inadequate at the present time for formulation of a definite theory, we believe that the final solution of the epilepsy riddle will be found in some such abnormality of brain cell function as that suggested above.

SUMMARY AND CONCLUSIONS

1 Experimental and clinical studies on the relationship of epileptic seizures to variations in the water and mineral exchanges of the body are briefly reviewed

2. Production of a deficit in the body water by any means tends to cause a temporary cessation of convulsions in severely epileptic children

3. Re-establishment of a positive water balance results in recurrence of seizures in such patients

4. Typical *grand mal* attacks can be induced in a high percentage of the mildly epileptic patients, but not in non-epileptic subjects, by giving water at the rate of from 2 to 5 c c per kilogram of body weight per hour while maintaining effective pituitary antidiuresis. This difference in response between non-epileptic and epileptic patients appears to be sufficiently specific to serve as a test in differential diagnosis in obscure cases

5. Dilution of the extracellular body fluids is considered to be essential to the induction of seizures under these conditions, because addition to the low-mineral diet of just sufficient NaCl to prevent dilution tends to prevent their occurrence

6. Mineral studies show that during periods of diuresis and freedom from seizures the excretion of Na and Cl greatly exceeds that of K.

7. In one series of experiments it was found that the K balance was strongly negative during convulsive periods, when water was being stored. At the same time Na showed a slightly positive balance

8. Since most of the K of the human body is held within the cells, this marked increase in K excretion, which manifested itself in the case of the severe epileptic from 2 to 36 hours before convulsions began to occur, indicates a "leakage" through the cell membrane. This phenomenon has not

been found to occur in normal subjects under similar conditions

9 These and other data referred to are tentatively interpreted as favoring

the view that the mechanism for controlling the semipermeability of the brain cell membranes is inherently defective in epilepsy

Modern Muscle Physiology and Circulatory Failure

By J. C. MEAKINS, M D , C.M., LL D., F R C P., F A.C P , *Montreal, Canada*

THE prevailing interpretation of circulatory failure, particularly when conceived as cardiac in origin, is usually founded upon an anatomical concept, the reason most probably being that the special senses are appealed to. The murmurs produced by valvular defects are readily heard or felt. The irregularities of rhythm are likewise recognizable either by palpation of the pulse or by graphic records such as the electrocardiograph. The rest of the disorders or deficiencies of function are covered by that all-embracing term, myocarditis. What this exactly means is hard to define and the term has probably done more to retard our investigation of circulatory disease than any other single factor. The cardiac muscle, the very main-spring of the circulatory system, has received but scant attention. It is a fact that whereas twenty years ago the stethoscope was the last court of appeal in cardiac diagnosis, now the electrocardiograph is the main arbiter. But no matter how meticulously the QRS and T deflections are studied the knowledge so obtained is but limited and what is worse it becomes almost Delphic in its oracular dogmatism, platitude being piled upon platitude.

Unless we continue to seek the complete truth of why cardiac muscle fails, the full understanding of circulatory disease can progress but little.

There is probably no realm of physiology that has attracted more attention during the past twenty years than has the elucidation of muscle contraction. The search for truth has been pursued with a single-mindedness of purpose, a generosity in controversy, and an open acknowledgment of mistakes that is seldom seen in scientific disputes but which is much to be emulated. This knowledge must now be applied to the pathological physiology of the heart. This is not the place to enter into a detailed description of the most modern conception of muscle physiology, but a brief account is necessary.

The primary constituents for muscle contraction are a labile form of organic phosphate called "phosphagen" and glycogen. The glycogen is obtained from the blood glucose through the action of insulin and oxygen. On contraction the glycogen is broken down into lactic acid and the amount of lactic acid is proportionate to the amount of muscular energy developed. In mammals there is no evidence that lactic acid is directly resynthesized into glycogen in the muscle, but it is carried to the liver where it is reformed into glycogen and re-enters the blood as glucose.

Presented at the San Francisco meeting of the American College of Physicians, April 7, 1932

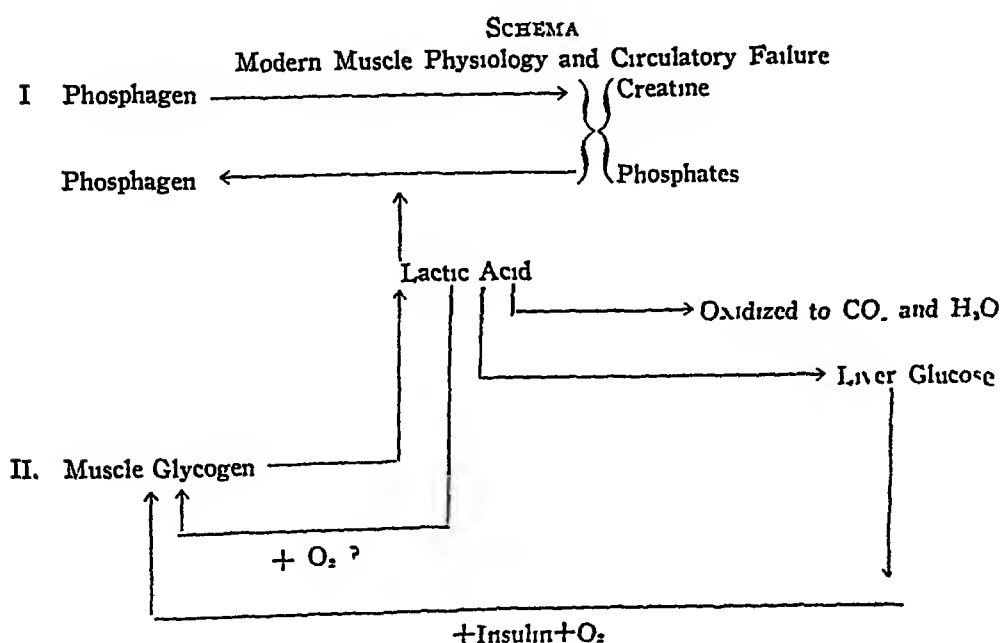

In addition, the pre-existing stores of carbohydrate in the liver are also discharged during the recovery period to be carried to the muscle as glucose, from which muscle glycogen is produced and stored locally. This last conversion requires the participation of insulin and oxygen.

Although lactic acid formation may be taken as an index of energy it does not occur immediately. During muscular contraction "phosphagen" is broken down into creatine and phosphate. This is the primary change by which energy is set free. It is after the contraction that lactic acid appears and during the period when the "phosphagen" is restored. The energy liberated by delayed lactic acid formation allows re-synthesis of "phosphagen", this, however, does not occur if lactic acid formation is impossible, as in a carbohydrate-free muscle, or in muscles poisoned with iodoacetic acid.

Such in very brief is our knowledge

of muscle physiology. In what manner can this be used to elucidate some of our problems of cardiac deficiency? As yet but little is known about variations in "phosphagen". So for the present our attention must be confined to a study of glycogen metabolism as this is such an important adjunct in "phosphagen" reactions.

During the past few years workers in our Department have directed their attention to this important subject. It will be noted from the schema that the vulnerable points in the glycogen-lactic acid cycle are in the conversion of lactic acid into glucose in the liver and that of the blood glucose into muscle glycogen by insulin and oxygen. It is not my purpose to go into all the possible causes whereby this cycle may be interrupted, but to confine my remarks to a number which are particularly pertinent to important problems in clinical medicine.

NORMAL VARIATIONS IN CARDIAC GLYCOGEN

It is known that cardiac muscle ordinarily contains a relatively high percentage of glycogen and that it is zealously conserved in a variety of conditions when the skeletal muscle glycogen reaches a low level. A good example is the high percentage of glycogen in the heart in diabetes whereas it diminishes considerably in the skeletal muscles in this disease. Kilbourn and MacLeod¹ demonstrated another interesting fact in that the primitive heart of the dogfish contains much more glycogen than the skeletal muscles or even the liver. The percentage of glycogen in the heart and in the skeletal muscles is not always in the same ratio. MacLeod and Prendergast² found in the dog that the heart percentage was the greater while in rabbits it was the reverse. Katz, Kerridge and Long³ also found in cats that the percentage in the skeletal muscle was the greater. But these ratios are not necessarily constant as MacLeod and Prendergast² demonstrated that during starvation the skeletal muscle glycogen decreased while the cardiac glycogen remained unchanged or even appeared to increase. This has been confirmed in rats by Lawrence and McCance.⁴ This would seem to indicate that cardiac glycogen would remain until other deposits were exhausted.

CARDIAC WORK AND GLYCOGEN CONTENT

Under normal conditions it has been found impossible to reduce the cardiac glycogen by direct energy demands provided there is an adequate supply of oxygen. G. T. Evans,⁵ in our Depart-

ment, has demonstrated this by exercising rats to an extreme extent and under no conditions of physical exercise without anoxemia was the cardiac glycogen below the normal resting levels. He has also shown that adrenalin injected intravenously in doses sufficient to produce a pronounced rise of blood pressure and a profound increase of cardiac rate does not deplete the cardiac glycogen content. This work was done with rats. It is conceivable that a tachycardia could be produced which might shorten the recovery period to such an extent as to interfere with the normal physiological cycle. As yet this has not been accomplished by this means and is probably more likely to be found in the hearts of larger animals.

OXYGEN CONSUMPTION

Experiments by Lovatt Evans⁷ and his co-workers have shown that the oxygen consumption of the heart is in proportion to the work done. When this is increased as by the injection of adrenalin the oxygen consumption likewise increases. Starling and Visscher⁸ have demonstrated that the oxygen consumption of the heart is determined by the diastolic volume and therefore by the initial length of the muscle fibres. In other words, under physiological conditions the oxygen consumption at a given diastolic volume is always the same but has no relation to the systolic volume. In reference to rate they found that a slow heart can do a given amount of work per unit of time more economically. But as the heart tires and its functional capacity decreases, its mechanical efficiency is diminished, i.e., although the total energy (as measured by oxygen consumption) liberat-

ed at any given initial length of fiber remains unchanged, the fraction of this energy which can be utilized for the performance of work progressively diminishes. To do the same amount of work the heart has therefore to dilate continuously, and the work is maintained constant at an ever-increasing cost in total energy.

GLUCOSE AND INSULIN REQUIREMENTS

The earlier works on the glucose requirements of the heart were undertaken before the present knowledge of muscle physiology and insulin was known and also before the present technique of the isolated heart-lung preparation was perfected. These early workers all came to the conclusion that glucose was utilized by the heart in the performance of work. The experiments of Bayliss, Muller and Starling⁴ definitely demonstrated that the RQ of the heart-lung preparation is 0.95. In order that the preparation may be kept in good condition for long periods it was necessary to introduce insulin and glucose. They found in the absence of the former that enormous concentrations of glucose were necessary to compensate for the insulin deficiency. They found that glucose without insulin did not disappear by combustion. Furthermore, insulin and glucose had no specific effect upon the metabolism since it changed only if cardiac work changed at the same time. In other words, insulin and glucose are necessary for efficient cardiac function which is dependent upon adequate glycogen supplies which are provided by these two substances plus oxygen. These results were confirmed by

Cruickshank and Shrivastava⁹ who established that the sugar utilization of the heart is increased by insulin and also by maintaining a high blood sugar concentration. They have also shown in the dog's heart that glycogen synthesis depends upon insulin dosage and blood sugar concentration. G. T. Evans⁵ has gone farther and has demonstrated in the rat's heart that the normal values of glycogen can be greatly increased by insulin and glucose so that the heart can be its own storehouse under proper conditions.

PATHOLOGICAL CONDITIONS

1 *Oxygen Deficiency* Katz and Long,¹⁰ using mammalian heart preparations, have shown that by reducing the oxygen supply to the heart there was rapid dilatation and failure of function. The contractions became feebler and conduction slower, but recovery was possible unless diastolic standstill had occurred. During some experiments undertaken in this Department to investigate circulatory failure caused by diphtheria toxin, G. T. Evans found that the striking feature was sudden death which could be prevented by artificial pulmonary ventilation. When this was not done and the heart removed rapidly just before death was expected, it was found that the heart was practically depleted of glycogen. In other words the sudden death appeared to be due to a respiratory failure with progressive anoxemia, producing a conspicuous reduction in cardiac glycogen. He pursued this point and found that the cardiac glycogen was practically wiped out in carbon monoxide poisoning and in acute asphyxia produced by occluding the

trachea This depletion may occur within a minute or so. He next attempted to find at what level of anoxemia this reduction occurred or whether it was a gradual process in proportion to the reduction in oxy-hemoglobin saturation. The easiest means of producing graded anoxemia is by reducing the oxygen percentage of the inspired air. He found that at 13, 11 and 9 per cent there was little or no change in the glycogen content of the cardiac muscle. Below 7 per cent, however, there was a reduction and below 6 per cent the glycogen was reduced to about one-third of the normal amount.

It has been appreciated for some time by both mountaineers and aviators that there is a critical level in high altitudes. This varies somewhat from man to man but in the most fit it is between 25,000 and 27,000 feet, or a barometric pressure around 300 mms which is equivalent to about 8 per cent oxygen in the inspired air and an alveolar oxygen of about 30 mms. Such an alveolar oxygen partial pressure after making allowance for a reduction of the CO_2 to 20 mms would saturate normal hemoglobin to about 70 per cent. It has been found in lobar pneumonia, bronchopneumonia, edema of the lungs and other acute respiratory causes of anoxemia that when the oxy-hemoglobin saturation is below 75 per cent serious circulatory symptoms arise and the patient seldom recovers.

These experiments have dealt entirely with oxygen want as represented by a blood supply adequate in amount but deficient in oxygen. There is, however, another group of cases which have to be considered, namely those in whom the blood saturation is adequate but

through some local condition in the coronary system a sufficient amount of blood cannot be carried to the muscle. The most outstanding examples are lesions due to inflammatory, degenerative or mechanical occlusion of the larger or smaller coronary vessels. Common examples are to be found in rheumatic or syphilitic myocardial disease, hypertension and arteriosclerosis. In all of these conditions the coronary blood supply is apt to become deficient when the cardiac capacity for work will progressively decline. But the most spectacular effects are produced by cyanide poisoning when, through sudden arrest of oxidation, muscle metabolism immediately ceases.

2. *Changes in pH* (a) *Acidosis* It has been shown by Katz and Long¹⁰ that with anoxemia there is a rapid accumulation of lactic acid in the muscles and circulating blood when pulmonary ventilation is obstructed. Whereas the skeletal muscle is capable of tolerating considerable quantities of lactic acid within it, the cardiac muscle has no such property. The mammalian heart becomes exhausted when lactic acid accumulates to an average concentration of 0.72 gm per cent, while in the skeletal muscle this may rise to an average of 0.252 gm per cent. Thus, in the heart the lactic acid content can increase only two and a half times over the resting or normal active muscle whereas in the skeletal muscle it may increase four and a half times. It would therefore appear as if the heart has a much greater susceptibility to accumulation of hydrogen ions and has a much poorer buffering power. This being the case, the cardiac muscle arrives at its critical pH much more quickly than

does the skeletal muscle. This is an important observation as it shows that the heart has a greater intolerance to oxygen debt.

On the other hand, experiments by G. T. Evans have shown that a rat can be placed in an atmosphere of eight per cent of CO_2 for three hours. This produced profound hyperpnea, but it is apparently so buffered that at the end of this period the cardiac glycogen has not been reduced below the normal average level. The two sets of experiments are, however, not comparable, as in the first instance the accumulation of lactic acid was brought about through oxygen want while in the second, oxygen want does not need to be considered.

In the experiments of Katz and Long it is to be presumed that there was in addition to the local muscle anoxemia a considerable increase in the lactic acid content of the myocardium. Therefore, it may be stated, other things being equal, that acidosis *per se* does not interfere with glycogen metabolism.

(b) *Alkalosis* G. T. Evans has shown that alkalosis up to the point which does not interfere with respiration produces no change in the cardiac glycogen, but if apnea or even deficient pulmonary ventilation ensues sufficient to produce an oxygen want, then cardiac glycogen rapidly declines. This result is not effective upon the heart *per se* as alkalosis but only indirectly through its interference with proper respiratory function.

Thyrototoxicosis That thyrotoxicosis has a profound influence upon the circulation is a well-known clinical observation. The exact mechanism whereby this is brought about insofar as the

heart is concerned is not so clearly understood. It has been shown by Andrus and his co-workers¹¹ that the heart of an animal intoxicated by thyroxin is far more sensitive to the withdrawal of oxygen than is the normal one. Similarly, they have shown that the amplitude of contraction is more easily depressed by sodium lactate than is the normal heart. Making a chemical examination of such organs both normal and intoxicated, it was found that in the latter the lactic acid was increased on the average by over 70 per cent, while the glycogen content was reduced by over 60 per cent. This would indicate that thyroxin had brought about an accumulation of lactic acid and a depletion of glycogen in the myocardium. These results have been confirmed by Lawrence and McCance⁶ who found that thyroid extract given by mouth reduces very greatly the glycogen of the heart and furthermore that the hyperthyroid heart is unable to replenish its glycogen stores even after high carbohydrate feeding. This is quite different from the skeletal muscle. As yet experiments have not been conducted to show what influence insulin plus carbohydrate might have in offsetting this important deficiency.

Diabetes Reference has already been made to the importance of insulin in the conversion of blood glucose into muscle glycogen. Cruickshank and Shrivastava⁹ have studied the action of insulin on the storage and utilization of sugar by the isolated normal and diabetic heart. They found that the diabetic heart perfused with diabetic blood did not utilize blood sugar and that this lost power was restored by perfusion with normal blood or by the

addition of insulin. And furthermore, that in the diabetic, insulin administered in physiological doses maintained the glycogen synthesis and brought the glycogen and muscle sugar-content towards the normal. It is quite clear from these experiments that insulin plays an important rôle in the maintenance of the cardiac glycogen.

Cardiac Disease The direct estimation of cardiac glycogen in those dying of heart disease is impossible unless the heart could be removed at the instant of death. It is unfortunate that glycolysis takes place so rapidly; otherwise, if glycogen were a more stable substance important direct observations would have been made long ere this. It is necessary, therefore, in attempting to reconstruct what is taking place in a human failing heart, to work in an indirect manner. There is no reason to doubt that in all conditions where there is a deficient oxygen supply to the myocardium either through desaturation of the blood that is supplied to the heart, or through interference with the quantity of blood that can reach the muscle, a reduction of cardiac glycogen occurs. The exact threshold of such depletion can not be determined, that every effort will be made to compensate for such, there is every reason to believe. But it is to be expected that there is a critical level beyond which it is dangerous to go. This has been shown in the case of acute anoxemia. Long and myself have found that in failing circulation due to cardiac disease there is an in-

creased amount of lactic acid present in the resting blood, and that this is in proportion to the degree of circulatory failure. It is, however, kept within reasonable limits but with each acute exacerbation of circulatory failure the lactic acid mounts in a very pronounced manner. But this cannot be tolerated for long; if it is not corrected within a short time cardiac function ceases. This is what probably happens in all cases of either acute or chronic heart failure. It must be appreciated that the accumulation of lactic acid in the circulating blood is but a reflection of what is occurring in the muscles, and as it has been shown above that the myocardium is intolerant of local changes of pH and accumulation of lactic acid through oxygen want, it becomes quite clear as to the reason of cardiac arrest under such conditions. Through the associated pulmonary and circulatory functional defects it has been found that cases with failing compensation are unable to increase their oxygen intake beyond a certain point, which point is roughly in proportion to the degree of circulatory impairment. This has been confirmed by Eppinger, Kisch, and Schwartz, 1927,¹² and again in 1930 by Harrison and Pilcher.¹³

In conclusion, we may summarize that there are three important known conditions which may lead to failure of the cardiac muscle to function properly through a defect in cardiac glycogen metabolism. They are oxygen want, thyrotoxicosis and insulin deficiency.

Fatal Cinchophen Poisoning

Report of Six Cases

By LAWRENCE PARSONS, M. D., and WARREN G. HARDING, 2ND, M. D., L. R. C. P.
and S. (Edin.). *Los Angeles, California*

IN a previous article we¹ reported four fatalities from the use of cinchophen. Three of the patients had been under a mail order treatment for chronic arthritis. All four cases exhibited subacute hepatic degeneration ("yellow atrophy"). Eleven similar cases studied at necropsy by others, presented analogous changes. Several cases subsequently reported, together with others that were overlooked in the preparation of the previous report, increase the total number of fatalities in the literature to thirty-two.¹⁻²⁰ Of this number twenty-six have been autopsied. In all of these cases the essential pathological changes were limited to the liver. Recently we have observed an alarming increase in the incidence of such cases in this vicinity. It is hoped that a report of such cases will call attention to the danger attending the use of cinchophen and its derivatives.

The clinical diagnosis of this entity following the appearance of jaundice is not difficult. The history usually reveals a female patient past middle age who has suffered from some arthritic

or neuritic condition of a chronic nature. Cinchophen or some proprietary "rheumatism cure" has been taken, following which the pain has been greatly relieved. After a short interval a progressive, painless jaundice appears associated with epigastric distress, pyrosis and vomiting. In the earlier stages a physical examination reveals a moderate jaundice and a slightly enlarged tender liver. As the disease progresses the liver gradually diminishes in size. Objective demonstration of the liver may be accomplished by an oxypertoneum procedure followed by a radiographic flat plate of the abdomen. In severe cases the patient may be comatose. Laboratory examinations may show albumin, casts and bile in the urine. Tyrosin and leucin crystals have been found in many of the severe cases. The icteric index is increased. The Van den Bergh test shows both a prompt positive and a delayed positive reaction. Frequently, a moderate secondary anemia is present.

REPORT OF CASES

Case I. Miss E. W., white, age 64, case no 153-172, entered the Los Angeles General Hospital, April 4, 1931, on the service of Dr. B. S. Frary, and died June 21, 1931. In August, 1930, she had noticed some swelling of her finger joints and upon the advice of a neighbor began taking six tablets of "Ren-

From the Department of Pathology, Los Angeles County General Hospital, Unit No 1, and the Department of Pathology, School of Medicine, University of Southern California. Received for publication, Nov 28, 1931.

ton's Hydrocin" daily. She continued this dosage for several months. Each tablet contains approximately five grains of cinchophen.²¹ In December, 1930, she was deeply jaundiced and the liver dullness was markedly decreased. There was slight abdominal distention and edema of the legs. The stools were of normal color. She had never had pain in the region of the liver or gall bladder. The jaundice gradually diminished until admission to the hospital. The physical examination at that time revealed a well nourished white female very slightly jaundiced but with marked ascites and edema of the lower extremities. The superficial veins of the abdomen were distended.

Laboratory examinations gave the following data. The urine was negative except for occasional granular casts. No leucin or tyrosin crystals were found. The phenolsulphonphthalein dye excretion test showed 25 per cent function in one hour.

The study of the blood showed Hemoglobin, 81 per cent, erythrocytes, 3,940,000, color index, 1.03, leukocytes, 9,800, polymorphonuclear neutrophils, 74 per cent, with a slight shift to the left. The icterus index was 22. The Van den Bergh test was promptly positive (direct), while the indirect was 2.1. The blood chemical findings were normal on admission but on June 6, 1931, the total non-protein nitrogen had risen to 60 mgm per 100 cc of blood, although the preformed creatinine was 1.5 mgm per 100 cc of blood.

Numerous abdominal tapplings were done, each with the removal of several liters (7 to 8) of cloudy, straw-colored fluid. On one of these occasions, after the removal of 8000 cc of fluid, 9000 cc of oxygen were introduced and an X-ray plate made, which revealed a very small liver shadow.

Owing to intractable ascites and pyloric obstruction, an omentopexy and a posterior gastro-enterostomy were done on June 18. The pylorus was about the size of the little finger, probably the result of an old ulcer. The gall bladder was normal. The liver was much smaller than normal, irregular, hard, and had the granular appearance of cirrhosis. No section was removed for microscopic study. The post-operative course was stormy, much vomiting occurred, and death ensued

June 21, 1931. Postmortem examination was refused.

Case II R. B., a white male, aged 70, case no 165-539, was admitted to the Los Angeles General Hospital, June 26, 1931, on the service of Dr. J. M. Lacey, and died July 8, 1931. For several years he had suffered with "rheumatism" and began taking "Renton" tablets²¹ two months before admission. In all, about 45 were taken in the first month but none since. The only untoward effect he noticed was marked itching of the skin after the first thirty tablets. He felt greatly improved until three weeks before entrance at which time he noticed the appearance of a progressive jaundice associated with weakness, loss of weight, and tenderness over the liver.

The physical examination showed Temperature, 98° F, pulse, 84, blood pressure, 130/64. The patient appeared well nourished and was deeply jaundiced. The area of liver dullness was decreased.

Laboratory examinations gave the following data. The urine showed four plus albumin but was otherwise negative. The Wassermann and Kahn reactions on the blood serum were negative. The erythrocytes numbered 4,450,000, the leukocytes 11,800, hemoglobin 80 per cent (Tallqvist). The blood chemistry was normal. The icterus index ranged from 143 on admission to 166 on July 3. The Van den Bergh test gave a prompt direct reaction and an indirect of 35.

Glucose was administered frequently intravenously in 10 per cent solution. The patient began vomiting after meals on July 3. He became comatose on July 7, and died on July 8, 1931. Permission for postmortem examination was refused.

Case III Mrs. V. D., a widow white, age 64, case no 166-678 entered the Los Angeles General Hospital July 4, 1931, on the service of Dr. F. W. Otto and died July 11, 1931. Following a fall ten years before, she had suffered with attacks of pain in the right side none of which were severe. She had never before been jaundiced. A week prior to admission jaundice was first observed. In March (1931) she had begun taking "Renton" tablets²¹ for "rheumatism" in her right knee. She stated she took twelve

tablets in all and that though they made her dizzy the "rheumatism" disappeared.

The physical examination revealed a somewhat stuporous, deeply jaundiced, rather obese woman. The temperature was 98° F; pulse, 80, respiration, 19, blood pressure, 142/72. The area of liver dullness was greatly decreased. No other abnormal findings were present.

The laboratory examination showed. Many tyrosin and leucin crystals, many pus cells and bile were found in the urine. The stool had a faintly yellow color. The icterus index was 200. The Van den Bergh test was promptly positive in the direct reaction and 25 in the indirect. The non-protein nitrogen was 54 mgm per 100 cc of blood, preformed creatinine, 17 mgm. The Wassermann and Kahn reactions on the blood serum were negative.

The patient gradually became comatose and died July 11, 1931. The *postmortem examination* was made by Dr J H Schaeffer, Assistant Coroner's Surgeon of Los Angeles County.

The liver was very small, about the size of two fists and weighed about 500 grams. The organ was firm and leathery, but not nodular. The capsule was pale, gray-green and finely wrinkled. The surface made by cutting appeared finely mottled, dark green and gray, somewhat resembling an obstructive biliary cirrhosis in the gross. The microscopic sections showed almost complete disappearance of the hepatic cells and replacement of the shrunken lobules by fibrous-appearing tissue. In some areas a more acute type of hepatic necrosis was present. The bile ducts were apparently increased in number and considerable round cell infiltration was present among them. The microscopic diagnosis was subacute hepatic degeneration. The common bile duct was almost completely stenosed at the ampulla but there was no distension above. The intestinal contents were faintly bile-stained. Many petechial hemorrhages were present over the pleura and pericardium.

Case IV J A G, a white male physician, age 56, was first seen by Dr J M Lacey on August 29, 1930 (case no 4072). During the preceding winter he had had an attack of pain in one foot and ankle, which

he believed to be rheumatism. He took Atophan for three or four weeks. This was followed by a severe generalized pruritis. This subsided, but marked jaundice developed, together with extreme weakness. Jaundice and weakness were present at the time of examination. He then had a rather severe anemia with a hemoglobin value of 29 per cent and an erythrocyte count of 2,350,000. A diagnosis of toxic hepatitis due to cinchophen was made. The jaundice subsided for a time and some improvement in health occurred. Severe jaundice recurred and he died February 15, 1931, with the physical findings of acute yellow atrophy of the liver. No *post-mortem examination* was made.

Case V Mr D, a white male, age 62 years, was seen by Doctor Lacey in February, 1930. He had had neuritis in his legs and was given two tablets of Atophan three times a day for three weeks by his physician. Severe urticaria developed, followed by marked jaundice. The physical examination revealed extreme icterus. The liver was not palpable. There was no fever. A diagnosis of acute hepatic necrosis due to cinchophen was made. An intravenous solution of glucose was given. Small doses of insulin subcutaneously and alkalis by mouth were administered. He died on the same day. *Post-mortem examination* was refused.

Case VI Mr J C, a white male, age 43 years, was seen by Dr Machlin on September 10, 1931, complaining of epigastric distress followed by vomiting. He had taken two hundred "Renton Hydrocin Tablets" during the preceding six months because of arthritis of the right hip. The total dose of cinchophen was hence one thousand grains.²¹

Examination revealed a well nourished man of forty-three years who was slightly jaundiced. The entire abdomen was tender but not rigid. The temperature was subnormal. The stools were clay colored. The remaining findings were not altered. A diet rich in carbohydrates was ordered. The jaundice became progressively deeper during the following forty-eight hours. He remained conscious until the time of his death on September 12, 1931.

At *autopsy* the body was extremely jaundiced. The thoracic viscera were icteric and showed multiple petechiae beneath the serosal

surfaces. The gastro-intestinal tract was negative. The liver weighed 780 grams. It was quite flabby and the capsule was slightly wrinkled. The cut surface was mottled with yellow, raised, hyperplastic areas alternating with depressed reddened areas. The bile ducts contained a clear, mucoid material. The microscopic sections showed an extensive necrosis of the polygonal cells with connective tissue replacement. There was a moderate periportal round cell infiltration. The hyperplastic areas showed swollen hepatic cells deeply stained with bile. Aside from a moderate cloudy swelling of the kidneys, the remaining viscera were normal. The cause of death was "cinchophen poisoning with subacute yellow atrophy of the liver."

SUMMARY

1 Six additional fatalities due to cinchophen are reported.

2 Four of the six cases resulted from the use of Renton's Hydrocin tablets, a mail-order remedy containing cinchophen.

3 The six cases conform to the typical clinical syndrome of this intoxication.

We are indebted to Drs. Lacey, Frary, Otto, Schaeffer, and Machlin for permission to publish their data.

Agranulocytic Angina—Report of a Case

With Bacteriological Study

By ALVIS E. GRIER, M. D., F. A. C. P., *Houston, Texas*

SINCE Schultz¹ in 1922 reported a peculiar type of necrosing angina with marked absolute and especially granulocytic leucopenia, there have been increasing numbers of these cases described in the medical literature. To this condition Schultz gave the name of agranulocytosis. Later Friedemann² changed this designation to agranulocytic angina. It would seem that Schultz's original terminology is the more fitting. We feel that a disease of such marked virulence deserves our closest study. It is for this reason we wish to report our case in detail. The case is as follows:

Mrs. H. C. A. (seen with Drs. P. V. Ledbetter and M. H. Mohle), white, American, aged 35, entered the Baptist Hospital, September 23, 1930, complaining of extreme restlessness, weakness and a severe infection of the mouth. On the day previously she had developed a sore mouth, followed by ulcerations on the hard palate and between the upper central incisors, high temperature, chilly sensations and weakness.

The previous history was negative with the exception of frequent attacks of sore throat for several years previously and glycosuria for the past year. Records of blood pressure systolic, 140, diastolic, 90, showed no abnormalities.

Examination revealed a well developed woman, 35 years of age, 5 feet, 6 inches tall, weighing approximately 155 pounds, blood pressure systolic, 140, diastolic, 90,

temperature 102° F., pulse, 100, respiration 22. She was very restless and prostrated. The physical examination was negative, except for marked reddening, swelling and small ulcerations on the hard palate, associated with considerable swelling and redness of the gums. The submaxillary and lateral cervical glands were swollen and slightly tender.

Blood examination showed leucocytes, 3,700; small lymphocytes, 70 per cent, large lymphocytes, 10 per cent, polymorpho-neutrophils, 9 per cent, eosinophils, 1 per cent, erythrocytes, 3,900,000, hemoglobin, 75 per cent; no abnormal red cells. Smears from the mouth showed Vincent's organisms. Urinalysis revealed a small amount of sugar. The blood Wassermann reaction was negative. A blood culture was negative. Blood chemistry normal. Bleeding time was 2 minutes, coagulation time, 5 minutes, and platelet count, 110,000. From this time onward the necrosis in the mouth advanced rapidly until the left upper alveolar process and the soft and hard palate were completely necrosed. During this period there appeared on the flexor surface of the right forearm, the anterior surfaces of the legs (figure 1) and the right malar area of the face, black areas, which resembled a dry leathery necrosis. The areas on the arms and legs extended rapidly, the one on the face slightly. Later they began to regress at the edges, leaving a rounded, irregular border. At no time was any suppuration nor pain noted. The temperature ranged from 101° to 105° F., and the pulse from 120 to 140 during the first 24 days. From her entrance to the hospital until October 17 she had received six blood transfusions without any improvement. On the evening of

Received for publication, Nov. 10, 1931

October 17, we began giving her daily 120 grams of raw fetal spleen in tomato juice, the following morning her total leucocytes were 1500, polymorphoneutrophils, 28 per cent, small lymphocytes, 63 per cent, large lymphocytes, 9 per cent, and the temperature was ranging from 103° to 105° F. Four days after beginning the fetal spleen the temperature had dropped to 100° F and leucocyte count was now 8000 with 80 per cent polymorphoneutrophils, 10 per cent small lymphocytes and 10 per cent large

became worse and her leucocyte count on the second day thereafter was 2700 with 53 per cent polymorphoneutrophils, which fell to 19 per cent by the seventh day. On the sixth day (Nov 16) it was decided to increase the fetal spleen to 180 grams per day. The leucocytes began to increase rapidly until by November 21 the count was 9000 with polymorphoneutrophils, 73 per cent. On this date she had a severe hemorrhage from the left external maxillary artery, which had been eroded by the

FIG 1 Areas of black, leathery consistency, extending into the deeper layers of the skin, borders rounded and irregular, regression centripetally, leaving dark pinkish margins which faded entirely as areas became smaller

lymphocytes. By referring to figures 2 and 3, further understanding of the progress will be facilitated. It will be noted that the clinical and hematological evidences of recovery were considerable until on November 10 it was decided to remove the extensive necrotic material from the mouth. At this time the patient was tremendously improved and gaining strength rapidly, the temperature was 99° F, total leucocyte count, 4000, polymorphoneutrophils, 63 per cent, small lymphocytes, 32 per cent, and large lymphocytes, 5 per cent. Following the removal of the necrotic tissue she rapidly

extensive necrosis in the mouth, and death seemed imminent for several hours. The necrosed area was tightly packed, and she rallied somewhat. On November 23 a blood transfusion was given. Considerable bleeding continued around the packing, and on November 29, another large hemorrhage occurred. Another blood transfusion was given, and the left external carotid artery was ligated. The bleeding stopped immediately but the patient died the next day. Following this last hemorrhage the total leucocyte count and the polymorphonuclear neutrophils increased until on the day of her

FIG 2 Progress of patient, showing temperature curve and hematological aspects Note reaction following exhibition of fetal spleen

death they were 34,500 and 97 per cent respectively. Such a count is the usual finding following severe hemorrhages. However, it is not an accurate appraisal of the total corpuscular content of the body because of the extreme fluid loss from the hemorrhage. But as we have heretofore outlined, the well marked leucocytic response to the increased fetal spleen intake took place before the hemorrhage occurred. Autopsy was declined.

EXPERIMENTAL INVESTIGATION

On October 20, 1930, three guinea pigs were injected intraperitoneally with 5 cc,

3 cc, and 25 cc, respectively, of Mrs H C A's blood. Two of the pigs were unaffected, but one died on the eighth day thereafter. The following table shows its blood reaction.

At autopsy of this animal nothing unusual was noted except that at the site of the injection on the abdomen there was an area about an inch in diameter of dark necrosis, which was identically similar to the areas on the patient's arms, legs and face. No changes were noted in the internal organs macroscopically. A culture was obtained from the heart's blood and we obtained three types of organisms. (1) Many gram-nega-

tive bacilli, (2) few gram-negative diplococci, (3) few gram-positive diplococci. We were successful in isolating the gram-negative bacillus and also the gram-negative diplococcus. The gram-negative bacillus hereafter will be referred to as bacillus 1A (figure 4). But we were unable to secure a pure culture of the gram-positive diplococcus, which died out on frequent transplantations. The cultural characteristics of these organisms may be found on charts I and II.

On October 23, 1930, two rabbits were inoculated intravenously with 2 cc and 25 cc, respectively, of citrated blood from Mrs HCA. Two uninoculated rabbits were used as controls. Blood counts were made on these rabbits from October 23, 1930, through November 5, 1930, and no changes were observed.

On November 6, 1930, blood counts were made on three guinea pigs previous to the intraperitoneal inoculation of each one with 0.5 cc of a 24 hour broth culture of the

FIG 4 Gram-negative, motile Bacillus 1A, obtained from the heart blood of guinea pig No. 1, which had been inoculated with patient's blood

different organisms recovered. Counts were made at the end of 6 and 24 hours and then every 24 hours for 6 days after the inoculation. Little change was noted in these counts which will be found below.

negative diplococci, a few gram-positive diplococci, and a few spirilla. By transfer and isolation a pure culture of gram-negative bacillus (to be referred to as *Bacillus* 1B) (see figure 5) was secured.

definite changes in the blood counts. Counts were made daily for 10 days and no changes were observed. However, we obtained a pure culture of gram-negative diplococci from the heart blood of guinea pig 9, which had been inoculated with the culture of gram-negative diplococci and gram positive diplococci.

On November 19, 1930, a guinea pig was injected intraperitoneally with 2 cc of broth culture of gram-negative *Bacillus* 1B.

On November 28, 1930, an effort to secure a pure culture of the gram-positive diplococci from the original culture was made by inoculating guinea pig 11 with 2 cc of broth

culture of gram-positive and gram-negative diplococci (with gram-positive diplococci predominating). On the next day, November 29, 1930, to lower the resistance of the guinea pig, 900 milliamperes seconds of x-ray exposure were given at cone distance and without filter. On the next day the same amount of exposure was given, and following the exposure, 3 cc of a broth culture of gram-positive and gram-negative diplococci were given intraperitoneally. On December 3, 1930, the guinea pig appeared very sick and during the day had an occasional convulsion. Two other exposures of x-ray of same amount were given on December 6

and December 8, 1930 Discontinued counts after December 9, 1930 Guinea pig recovered

On the morning of December 1, 1930, guinea pig 5, which had been inoculated with 0.5 cc of broth culture of gram-negative bacillus 1A on November 6, 1930, was found dead. Results of autopsy were as follows:

Considerable peritoneal congestion and redness were noted with a moderate amount of free fluid in the peritoneal cavity. There was moderate injection of the small intestines. Kidneys externally were slightly injected. Liver was very noticeably injected and red, almost nutmeg in appearance. Gall bladder was distended and did not empty readily. Cultures were taken from the peritoneal fluid and from the distended gall bladder. The stomach was normal. The spleen was dark red and slightly swollen. Pancreas was normal. The heart was normal. The lobe of the left lung was hard, dark, and hemorrhagic. In the right lung there was more extensive and scattered involvement, similar to that noticed on the left side, with some pleural ecchymosis. Cut section of the lungs showed a moderate amount of air with clear, light yellow fluid exuding on pressure, as well as considerable amount of bloody fluid.

From the heart's blood a pure culture of a gram-negative bacillus was recovered which we will hereafter refer to as Bacillus 1C. (See figure 6) The peritoneal fluid and gall bladder were sterile.

During the remainder of December we alternately transferred our organisms 1A,

1B, 1C, 2, 3 and 4 on dextrose broth for three days and agar three days. We were able to keep luxuriant growths of the gram-negative bacilli 1A, 1B and 1C. The diplococci 2, 3 and 4 grew less abundantly. In an effort to revivify the organisms we planted each of these on dextrose broth for three days, transferred to gelatin for three days and then to agar slants. The bacilli 1A, 1B, 1C, seemed to have been benefitted by the process while the diplococci were not.

Guinea pig 12 was inoculated intraperitoneally on January 7, 1931, with $\frac{1}{2}$ agar slant of the gram-negative Bacillus 1C. A preliminary blood count showed red blood cells, 4,800,000, white blood cells, 8,800, small lymphocytes, 91 per cent, neutrophils, segmented, 9 per cent. Another blood count was made on January 8, 1931, at 4:45 P.M. and showed red blood cells, 4,740,000, white blood cells, 4,800, small lymphocytes, 78 per cent, large lymphocytes, 1 per cent, neutrophils—segmented, 20 per cent, and stabs, 1 per cent. The guinea pig was found dead early the next morning and the necropsy findings were as follows:

Esophagus and trachea negative. Pleural cavity contained about 0.5 cc of blood-tinged fluid. There was a small ecchymotic area over the left parietal pleura. The peritoneum was slightly injected. The entire liver surface was covered with a white gelatinous material, and on the inferior surface of the right lobe was a large blotchy grayish-white area. The internal surface of the liver was of normal color and consistency. The spleen was negative. The

stomach negative. On the inferior medial surface of the left kidney was a blotchy area of the same color as that on the liver, approximately 0.5 by 2 cms in diameter. Large and small intestines were negative. The peritoneal cavity contained about 10 cc of blood-tinged fluid. Culture from the heart blood revealed a gram-negative motile bacillus identical with 1C.

Guinea pig 13 was inoculated intraperi-

The peritoneal cavity contained about 15 cc of blood-tinged fluid. There was a small blotchy area on the external surface of the right lobe of the liver. The pancreas and spleen were negative. Kidneys negative. Multiple ulcers in the mucosa of the greater curvature of the stomach. Small intestine negative. Large intestine negative except for a perforation about 1 by 1.5 cms. There were about 5 cc of serofibrinous blood-

FIG 6 Gram-negative, motile *Bacillus* 1C, obtained from the heart blood of guinea pig No 5, which had been inoculated with gram-negative *Bacillus* 1A.

toneally on January 7, 1931, with one agar slant of the gram-negative *Bacillus* 1C. A preliminary blood count on January 7, 1931, showed red blood cells, 4,810,000; white blood cells, 6,800; small lymphocytes, 96 per cent; large lymphocytes, 1 per cent; neutrophils—stabs, 2 per cent; and segmented, 1 per cent. On January 8, 1931, at 4:45 P.M., another blood count showed red blood cells, 4,670,000; white blood cells, 3,800; small lymphocytes, 61 per cent; neutrophils—segmented, 38 per cent; and stabs, 1 per cent. The pig was found dead on the morning of January 9, 1931, and the following findings at autopsy were found:

tinged fluid in the pleural cavity. Both lungs were negative except for a rather marked degree of paleness. Trachea and esophagus were negative. *Bacilli* 1C obtained by culture from the heart blood.

Guinea pig 14 was inoculated intraperitoneally on January 7, 1931, at 9 P.M., with two slants of the gram-negative *Bacillus* 1C. A preliminary blood count showed red blood cells, 4,608,000; white blood cells, 6,200; small lymphocytes, 89 per cent; large lymphocytes, 2 per cent; neutrophils—segmented, 8 per cent; and stabs, 1 per cent. Another blood count made at 4:45 P.M. on January 8, 1931, showed red blood cells

Guinea pig died during night of Jan 12, 1931

injected There was a moderate amount of subserous injection on the most dependent portion of the stomach. The gastric submucosa showed a rather diffuse petechial and hyperemic injection in the most dependent area. The liver was covered with a grayish-white exudate and there were scattered, discrete, slightly injected areas over both dorsal and ventral surfaces. The pancreas was markedly injected and hemorrhagic. The spleen was normal. In the lung were small hemorrhagic areas scattered throughout. The pleural cavity contained a small amount of hemorrhagic fluid.

Guinea pig 16 Abdomen was filled with serosanguineous fluid. There was a small perforation in the large bowel. The large and small intestines were markedly injected with patchy diffuse hemorrhagic areas throughout. On the superior and inferior surfaces of the liver were small scattered grayish-white and hyperemic areas. The stomach showed marked subserous injection, the mucosa was markedly injected with diffusely scattered hemorrhagic areas. The right kidney revealed a few scattered hemorrhagic areas on the medial surface. There

was a small amount of blood-tinged fluid in the pleura. Throughout both lungs were many hemorrhagic areas. The entire surfaces of spleen and pancreas markedly injected.

Guinea pig 17 Dead in approximately 36 hours after injection. Grossly Serosifibrinous exudate in peritoneal cavity, hyperemia in omentum and over greater curvature of stomach. Very little inflammatory reaction elsewhere. No petechiae. Brain negative. Chest two or three small hemorrhagic foci in lungs, none in pleura. A very small amount of blood-tinged fluid was found in left pleural cavity. All other organs negative. Lymph nodes normal in abdomen and other parts. Microscopically Peritoneal exudate almost entirely composed of bacteria, a very few polynuclear leucocytes were present in fibrin. Lungs A few small hemorrhages, no inflammatory reaction. Kidneys normal. Spleen normal. Liver slight edema of the surface from the proximity of the peritoneal inflammation. Otherwise negative.

On January 15, 1931, a preliminary count was made on guinea pig 18. This was inocu-

Guinea pig died at 12 45 P M

lated intraperitoneally with ¼ slant of the gram-negative Bacillus 1C. Counts were made twice daily until death.

At autopsy a small amount of fluid and considerable fibrin were found in the peritoneal cavity. Omentum showed inflammatory thickening. All organs normal except for the slight, superficial inflammatory reaction of the peritoneal surfaces of the liver, stomach, and intestines. No petechiae. Microscopically Lungs normal. Kidneys normal. Liver Edema of superficial portions associated with the peritoneal inflammation, otherwise hepatic tissue was normal. The capsule showed swelling of the endothelium and fibrinous exudate infiltrated sparsely with leucocytes. At intervals there were collections of pyknotic nuclei close together, some lymphocytic, but most apparently the nuclei of degenerated, polynuclear leucocytes. Spleen normal. Omentum hemorrhage into the fat cells and between them. Inflammatory reaction was similar to that described on the liver capsule. There were a smaller number of polynuclears, and a greater proportion of plasma and lymph cell types, than would be expected in such an acute process. No true pus.

Guinea pig 19 was inoculated on January 27, 1931, with ½ slant of the gram-negative Bacillus 1C which had previously been revived. A preliminary count was made and another shortly before death on Jan 28, as follows:

We recovered from the heart's blood gram-negative bacilli in pure culture. The autopsy findings were as follows:

Abdomen. There was a large quantity of yellow serous plastic exudate covering all organs. On the inferior border of the stomach were scattered hemorrhagic areas. The greater omentum was markedly injected. There was considerable injection of the mucosa of the pyloric portion of the stomach. The entire small intestine was markedly injected. There were scattered localized hemorrhages involving all surfaces of the intestines. Slight amount of serosanguineous fluid in pleural cavity. The lungs showed scattered, discrete, subpleural ecchymoses. There were a few scattered hemorrhagic areas in the right lower lobe.

Rabbit 5 was inoculated intraperitoneally on February 5, 1931, with ½ agar slant of the Bacillus 1C. The preliminary and subsequent counts were as follows:

At 10 A.M. on Feb 7, 1931, a culture was taken from this rabbit's heart. Later a pure culture of a gram-negative, motile bacillus, similar morphologically to Bacillus 1C, was recovered. The rabbit was killed at 10:30 A.M. on Feb 7 and bone-marrow smears (figure 8) were made from the sternum. At the same time bone-marrow smears were taken from a normal rabbit (figure 7).

In the normal rabbit's bone-marrow there was a considerable preponderance of myeloid over erythroid cells, whereas, in in-

In this connection it is to be remembered that the circulating blood of a normal rabbit contains 10 to 15 per cent eosinophilic leucocytes.

No marked gross changes were observed in rabbit 5 at autopsy. Microscopical examination. Liver. Intense congestion and marked parenchymatous degeneration evenly distributed, moderate amount of fatty degeneration, no cellular infiltration, the nuclei of the hepatic cells were slightly swollen and pale but were on the whole well preserved. Kidney. Very marked parenchymatous degeneration throughout renal parenchyma. The degenerative changes were most marked in

outer wall of Bowman's capsule and the emerging duct were approximately normal. No changes were seen in the endothelial cells. No cellular infiltration nor vascular changes were present. Spleen. There was swelling and edema of the reticular cells, no other abnormality. Lymph node. One small section of this showed changes similar to those in the spleen. Lungs. Negative except for congestion and edema. No hemorrhagic changes in any of the organs.

Guinea pig 20 was injected on March 18, 1931, intraperitoneally, with $\frac{1}{2}$ slant of gram-negative *Bacillus* 1B. A preliminary count was made on the morning before the

inoculation and another at 4 P.M. The guinea pig died that night

At autopsy 10 cc of serofibrinous fluid were found in the peritoneal cavity. The entire surfaces of both large and small intestines, which were covered with a thin purulent exudate, showed slight ecchymotic areas with occasional injection. The stomach was negative. The spleen and pancreas were negative. On the left lobe of the liver were five, small ecchymotic areas. The kidneys were negative. The heart was negative. The left lung showed generalized injection. The right lung was negative. The esophagus negative. A pure culture of gram-negative motile bacilli was recovered from the heart blood.

DISCUSSION

In this study of one case of agranulocytic angina, and the ensuing follow-up experiments, it was our hope to observe some factor which might be of interest and value in combating this

disease or in throwing light on its activities.

The rôle of the spleen in fetal and in post-natal hemopoiesis, its probable complementary correlation with the bone-marrow, its capability for myeloid metaplasia in myelosis and bone-marrow sclerosis,³ its almost uniform changes in leucopenic diseases, as well as the rarity with which septicemic diseases produce abscesses in its structures, led us to consider the likelihood of fetal spleen being of value in agranulocytosis. We feel as does Moynihan⁴ that the theory that spleen-pulp secretes a substance normally restraining white cell formation is entirely too superficial, and the experimental evidence to support it is not at all conclusive. Pfeiffer and Marx⁵ in investigating the formation of immune substances

FIG 7 Bone-marrow of normal rabbit

in cholera found the spleen and the marrow of the long bones to contain a far larger proportion of immune substances than any other part of the body, and we know the resistance to infection is less in the early months after splenectomy. Also Hektoen⁶ affirms that antibodies are formed chiefly in the spleen, lymphatic tissues and bone-marrow. Carpenter⁷ in 1900 reported that splenic extract was of value in treating typhoid fever and malaria and found the leucocytes were increased.

In this case the use of fetal spleen was followed by an interesting reaction. Of course we do not know whether it was related or coincidental. In two

other cases of agranulocytosis to be reported elsewhere, there was an even more decisive and prompt rise in the polymorphonuclear leucocytes after the administration of fetal spleen. In one case of aplastic anemia, one case of severe leucopenia following deep roentgen-ray therapy, and two cases of myeloid leukemia, no changes were noted in the white cells, after giving fetal spleen over a considerable period.

Had the left external carotid artery been ligated earlier as a precautionary measure against hemorrhage from the left external maxillary artery, we feel that the patient might have recovered.

Specific agglutination tests (chart III) would indicate that the gram-

FIG 8 Bone-marrow of rabbit No 5, which developed a severe granulocytopenia following injection with Bacillus 1C. Note the striking depletion of myeloid cells.

Note that Bacillus 1A, Bacillus 1B, Bacillus 1C respectively were agglutinated by *Bacillus coli communior* serum, *Bacillus coli communior* was agglutinated by Bacillus 1C serum, which latter, also, agglutinated Bacillus 1A and Bacillus 1B.

negative, motile Bacillus 1C should be classified as the *bacillus coli communior*. The gram-negative bacilli, 1A and 1B, obtained from the guinea pigs inoculated with the patient's blood, and from the necrotic tissue in the patient's mouth, respectively, possessed quite similar morphological, staining, cultural and fermentative reactions with the gram-negative bacilli 1C. We believe them to be the same organism. However, the bacilli 1B and 1C formed no gas with saccharose, whereas the pri-

mary bacilli 1A did. *Bacillus coli communis* forms no gas with saccharose but *bacillus coli communior* does. Bacillus 1B formed no gas with trehalose, which is at variance with its reaction with the colon group. All three organisms produced a small amount of gas with inosite, whereas the colon group ordinarily does not. These tests were repeatedly checked to insure their accuracy.

The cultural characteristics were similar to the colon group in the main details. However, the production of indol

by *Bacillus* 1A and *Bacillus* 1C was slight and with *Bacillus* 1B absent. There was also a slight, delayed liquefaction of gelatin. In these findings they differed from the colon group.

The gram-negative organisms, 1A, 1B and 1C, possessed definitely evident virulence and ability to repeatedly initiate a pronounced granulocytopenic blood reaction in guinea pigs and rabbits. In one rabbit, at least, very evident changes were noted in the myeloid elements of the bone-marrow at autopsy. It would seem in this case that the production of polymorphonuclear neutrophils in the bone-marrow was tremendously depressed.

The autopsy findings in eleven animals (ten guinea pigs and one rabbit) reflected certain findings in common. In the guinea pigs, which were injected intraperitoneally, the peritoneal cavity contained a moderate amount of serosanguineous fluid. The peritoneum was hyperemic, and a grayish-white, at times a yellowish, plastic exudation was noted. Especially on the peritoneal surface of the liver was the grayish-white exudate with hyperemic areas seen. In this locality the exudate was at times almost gelatinous in character, and ecchymotic spots were observed under the hepatic capsule. In the rabbit's liver parenchymatous degeneration and intense congestion were noted microscopically. There was also some fatty degeneration. There was no cellular infiltration. The small and large intestines were injected and hyperemic, and occasional areas of grayish-white exudate and ecchymotic spots were found. Especially about the ileum was this seen. Perforations were twice noted in the large

intestines. These perforations resulted from small perforating ulcers, arising from the mucous membrane, and were not traumatic. The mucous membrane, especially in the ileum, was hyperemic in three guinea pigs. In the rabbit's intestine no changes were noted macroscopically nor microscopically. On the gastric serosa, hyperemia, grayish-white exudation and rare ecchymotic spots were found. In one pig a small ulcer of the mucous membrane was found on the greater curvature near the pylorus. In one instance the gastric mucosa was injected with small hemorrhagic areas under the mucous membrane. The spleen in three animals (two guinea pigs and the rabbit) was somewhat swollen and very dark red in color. Swelling and edema of the littoral cells of the rabbit's spleen were quite apparent in the stained specimen. In this animal one lymph gland was sectioned and the same findings as in the spleen were noted. In five animals definite renal changes were observed consisting of swelling, subcapsular hyperemia, and blotchy localized hemorrhagic areas. In one pig a definite infarct was found in the kidney. In the rabbit's kidneys, parenchymatous degeneration, especially of the convoluted tubules, was found. No abnormalities were noted in the pancreas except in two cases, in one, some surface hyperemia, in the other marked injection and small hemorrhages throughout. In nine animals definite pathology was found in the lungs and pleurae. In six of these, serosanguineous, fibrinous exudation was noted in the pleura and in two, subpleural ecchymoses. Hemorrhagic areas moderately scattered throughout the lung tissue were noted

in five cases, in one guinea pig, a consolidated pneumonic area in the base of the right lung and in two, small hemorrhagic infarcts. Microscopically, considerable congestion and edema were noted in the rabbit's lungs and pleurae. No changes in the heart and thoracic vessels, esophagus, and trachea were observed. In every animal (ten guinea pigs and one rabbit) injected with the gram-negative *Bacillus* 1C, the organism was recovered from the heart's blood in pure culture following the animal's death. The bone-marrow of one rabbit showed a considerable depletion of myeloid cells, without any striking abnormalities of the erythroid cells. This was the only bone-marrow smear made.

There is considerable similarity between the necropsy findings in these animals and those of agranulocytic angina. In this latter disease the findings are: Subpleural and subpericardial hemorrhages, pleural exudation, hemorrhages and broncho-pneumonic areas in the lungs, cloudy swelling and fatty degeneration of the liver, moderate swelling and parenchymatous degeneration of the kidneys, some proliferation of the reticulo-endothelial cells of the lymph glands and spleen, depression of bone-marrow leucopoiesis, ulcerations of the gastro-intestinal tract, as well as in the oral cavity, vulva, vagina, cervix and rectum.

COMMENT

If we knew more about the pathogenesis of agranulocytic angina we might combat its ravages more successfully. We know that toxic substances expend their baneful power in several ways: some on the circulating leuco-

cytes, others upon their formative tissues; while a few act upon both. The action may be one of stimulation, so that a leucocytosis results, or it may be one of inhibition, and result in leucopenia. In pernicious anemia the poisonous action on the bone-marrow affects the white cells as well as the red cells, so that a very low white count is the rule, in hemolytic jaundice, on the other hand, the action on the bone-marrow is one of stimulation and leads to an out-pouring of leucocytes (leucocytosis). Florence Sabin³ has shown that leucocytosis involves both an increased delivery of cells from the bone-marrow (chemotactic factor) and an increased maturation of the delivered myelocytes (maturation factor) into the normal granulocytes (polynuclears, eosinophils and basophils). Therefore, this concept of leucocytosis and leucopenia postulates the infecting organism as introducing both a chemotactic and a maturation factor when a leucopenia follows a temporary leucocytosis. This condition has been proved to follow the injection of inactivated typhoid bacilli into a rabbit; the marrow and blood first show a leucocytosis, followed by a leucopenia. It has been proved that the mechanism of leucocytosis in an infection is due to an increase of the substances in the body that afford the normal stimulus, rather than some substance from the bacteria. The relationship of the degree of the leucocytosis to the resistance of an animal in infection has been repeatedly confirmed since Metchnikoff, and thus, as long as none of the substances involved in these reactions are known, variations in response of the body must be studied in terms of the amount of

the infection and, possibly, differences in the power of the hemopoietic tissues to respond. The reticulo-endothelial system is the locality for the formation of immune bodies, and as a part of that system the pulp-cells or the spleen are concerned in the manufacture of the immune substances with which the body resists infections. Immediately after splenectomy or in certain diseases with splenomegaly and leucopenia (kala-azar) it is impossible to develop immunity. It seems, therefore, that the spleen affords great aid in resisting infective processes. When we call to mind the frequency of pyemic and bacteremic states, the rarity of suppurative disturbances in the spleen is truly remarkable. It can only be explained on the assumption of strong bactericidal properties on the part of the spleen.

Pathological conditions in the bone-marrow may be divided into three groups: first, conditions of simple leucocytosis and leucopenia together with secondary anemia and aplasia, wherein no deviation is noted from the normal development of the cells; second, states like pernicious anemia and leukemia, in which immature cells come into the blood stream; third, conditions in which there has been an invasion of the marrow (replacement, necrosis, hemorrhage).

Normal bone-marrow architecture and normal bone structure have been found at autopsy in cases of agranulocytic angina. We observed in one of our cases the appearance of immature white cells (myelocytes, metamyelocytes) in the blood stream at the time of intense neutropenia. Although a greatly decreased number of granulocytes has been found in the bone-mar-

row at these autopsies we know that immature cells appear in the blood stream in more or less numbers. It would seem that there is an analogy between the state of the granulocytic function of the bone-marrow and the granulocytes in agranulocytic angina to that of the erythropoietic function of the bone-marrow and the red cells in pernicious anemia. However, since cases of agranulocytic angina recover and the blood stream returns to normal, the hypofunction must at times be temporary. Undoubtedly, either an infective or a toxic agent has temporarily paralyzed the granulopoiesis in the bone-marrow, or there is some substance which is lacking in the blood stream which would, if present, stimulate the bone-marrow to granulocytic activity. Of course, we know there is an intense infection present but the questions are, which is the primary organ involved, bone-marrow, spleen, reticulo-endothelial system, or, are several or all of them involved, or does the destruction of the mature granulocytes take place in the blood stream faster than the bone-marrow can manufacture them? If this latter condition were true we would find a considerable degree of granulocytic elements present in the bone-marrow in these cases. The reverse has been found, the marrow shows a striking depletion of granulocytic cells. We may assume therefore, that some other factor or factors are at work in the severe granulocytopenia than destruction of the leucocytes in the blood stream. We must look elsewhere. We have excluded the bone-marrow by the facts heretofore enumerated. Rosenthal and Spitzer² have shown that in the granulocytic an-

mal immune bodies develop normally, whereas, if the reticulo-endothelial system is blocked with colloid iron, immunity is greatly diminished, and, if the spleen is also extirpated, immunity ceases. The histopathology of the spleen in agranulocytic angina shows marked involvement of the splenic pulp (the reticulo-endothelial area). In most of the diseases characterized by a constant leucopenia there is a predilection for involvement of the splenic pulp. The Malpighian follicles show slight and inconstant changes in these diseases. If the spleen alone were involved in agranulocytic angina, the reticulo-endothelial tissues elsewhere in the body would soon take up its function of antibody formation, and this disease would, perhaps, not be so fatal. It would seem that the reticulo-endothelial system (in the spleen, liver, bone-marrow, lymph nodes, lymphoid tissue generally) is paralyzed by a toxic or infective agent, which may or may not be specific, and therefore immune bodies are not formed, and the granulocytogenic bone-marrow is not stimulated. In this connection it was interesting to note in the differential count of one of my cases, the increase of the monocytes (products of the reticulo-endothelial system) as the mature granulocytes (segmented forms) began to appear more abundantly in the blood stream as the patient improved, whereas they had previously disappeared. This of course shows evidences of re-

newed activity of the reticulo-endothelial tissues and increasing antibody formation. It was noted in this case that the monocytic cells began to increase in the blood stream six days before any increased signs of bone-marrow activity (increase in granulocytes) began. Antibody formation, it would seem, was beginning and the toxemia being combated. With the increasing control of the toxemia the severe effect of the infection on the bone-marrow granulopoiesis was lifted.

There is nothing impossible in conceiving that some toxins will affect the cells of the spleen-pulp, principally or exclusively, and cause degeneration therein. Then, the blood passing through the liver to the heart and lungs, without losing its toxic character, comes in contact with the cells in the sinusoids of the bone-marrow and may interfere with its granulopoiesis. If the toxin represses the bone-marrow granulopoiesis, leucopenia will result.

We would suggest that agranulocytic angina is not a disease entity, that it is a symptom-complex due to a paralysis of the reticulo-endothelial system from bacterial toxins, inhibiting or stopping the formation of some agent necessary for the stimulation of bone-marrow granulopoiesis.

It is with pleasure that I acknowledge the valued help of Dr Violet Keiller, Dr H N Gemoets, and our technicians, Mrs Louise M Blalock and Mr A W Owens, in this work.

The Importance of Stressing Man as a Social Being

“ONE of the wholesome signs of our times is the increasing stress which we are placing on man as a social being. Yale University is founding an institute of human relations to study the individual in his contacts with people around him. A fundamental part of this study is the start which the infant and pre school child gets in adapting himself to those around him. Every healthy child begins life with an assertion of his ego. Unfortunately he often does not learn till manhood that he is not merely an individual, but a member of a group. Home, school, neighborhood, professional circle, social set make progressively greater demands on him to consider their rights and comfort and desires. Until he has learned this lesson he is not much good to anybody. The academic, business, and social worlds have little time or patience with human material that needs special processes to make it marketable.”

The Typhus-Spotted Fever Group

By NOXON TOOMEY, M D . F A C P., *Palmyra, Mo*

AMONG plagues of great economic importance, typhus fever has had a long and historically prominent place. Particularly during the Middle Ages, the Renaissance, and the early decades of the Industrial Era was typhus most prevalent. However, not even today is typhus a whit less devastating than formerly, whenever war, famine or civic commotion gives it an opportunity to override its barriers.

Typhus fever has, since 1837, been recognized as a disease entity, an exanthematic entity, without apparent kinship to the other exanthematic fevers, or the other continued fevers of short or long duration. Separated initially by Gerhard and Pennock, and by Still, independently, from other infections, by clinical means alone, the typhus did not become categorized with any of the older known diseases after bacteriologic methods afforded a means for establishing certain group relationships among the infections. This continuance of typhus as a unique type was due to the fact that there had not been, or at least not until very lately, any acceptable evidence concerning the identity of its pathogen. Thus typhus continued as a fever not only associated with famine and other civic calamities, but also as typically an acute exanthematic fever of unknown cause. It not infrequently

shared with cerebrospinal fever, and the Rocky Mountain spotted fever, the colloquial appellation of "spotted fever." It was natural, therefore, that the recently discovered fevers of spotted character and typhus-like course were studied in comparison with the typhus fever, and were more or less closely identified with the latter; the typhus always being advanced as the historically appropriate type of the group. The typhus-spotted fever group, although mentioned in a general way during the past few years, has not been discussed in a systematic or comprehensive manner. Hence there is need now to set forth, as well as possible, a summary of what may at present be recognized as the typhus-spotted fever group of diseases. However, as several of the fevers belonging to the group have been but imperfectly studied clinically, with data of bacteriological and immunological character completely wanting, it is not possible to do more at present than to call attention to the existence of the lesser known fevers, and to indicate in a general way their presumptive relationships as deduced from the meager data known concerning them. The purpose of this paper is, therefore, to present a concise survey or general portrayal of the group, with some special consideration given to the newly discovered (but by no means unimportant) diseases

that have not yet been accorded a place in general medical literature. As the better known diseases of the group have an easily available literature they will receive the briefest possible consideration consistent with this purpose.^{22, 40}

The typhus-spotted fever group may at present be set forth as comprising the following distinguishable entities and varieties

1 A—Typhus fever (louse borne and flea borne)

Old World (Classical) typhus (louse borne)

Baltic-Russian-Chinese strain

Balkan-Asia Minor strain

Tabardillo of Mexico and northwestern South America

Endemic Typhus (flea borne)

Brill's Disease of the eastern United States⁸

Endemic typhus of the southern United States (Maxcy)^{50, 53, 70}

Endemic typhus of western Europe (Netter and Blaisot)^{27, 52}

São Paulo strain (Piza and DaRocha-Lima)⁷⁵

Shop typhus of Malasia (Fletcher)^{84, 49, 95}

Endemic typhus of Australia (Hone)⁴¹

Endemic typhus of South Africa (Wicht)

B—Trench fever (louse borne)^{24, 11}

2 The Typhus-like tick fevers (tick borne)

Spotted fever of the Rocky Mountains

Malignant (Montana - Wyoming) type (Wilson and Chowning)

Intermediate (Gastrointestinal) type of Colorado and Utah (Becker)¹⁶⁴

Mild type (Maxcy)

Acute mild type (Idaho-Oregon)

Protracted mild type (Nevada-Utah)

Mid-zone strain (Kemp)²²³ (Toomey)²³⁰ (Reimann)²³¹

Typhus-like (Eastern - Southeastern States) type (Rumreich)^{217, 224}

Fièvre boutonneuse (exanthematic fever) (Conor and Bruch)

Kumaun tick typhus of the Himalayas (Megaw)

Tick-bite fever of Natal (Pretorian ten day fever) (McNaught)

Inuga fever of Portuguese East Africa (Kudicke)

Port Elizabeth fever of South Africa (Scroggie and Gray)

Guacarapa fever of Venezuela (García)

3 A—Tsutsugamushi disease (mite borne) Japanese-Korean flood fever (Palm)

Scrub typhus of Malasia (Dowden) (Noc)

Pseudo-typhus of Sumatra (Schuffner)¹⁰

Lymphatic pseudo-typhus (Mossman fever) of Queensland (Smithson)¹⁰

B—Ship (Rat mite?) typhus (Plazy, Marcon and Carboni) (Shelmire and Dove)^{11, 41}

C—a American mountain tick-fever (Toomey),²²⁵ b Benign rickettsial disease (Toomey)

4 Reduvind scarlatinosis (transmitted by Reduviidae)

Macular type (Toomey)

Acute lichen planus type²

HISTORICAL

It was by the students of the newly discovered typhus-like spotted fevers that comparative studies in this group were first undertaken. Thus the tabardillo of Mexico and the typhus-like fever described by Brill⁸ were studied in relation to Old World typhus, and were found to be of similar pathogenic (immunologic) nature, but to have fixed varietal differences (Anderson and Goldberger,^{9, 12} etc.) Similarly the spotted fever of the Rocky Mountains was soon after its discovery compared with tsutsugamushi disease, a spotted fever of Japan.³⁰ Likewise spotted fever of the Rocky Mountains was compared with typhus fever, with which it had been observed to have a somewhat general resemblance.^{9, 57, 64} It was not, however, until the tick borne typhus-like fevers became somewhat known (after 1917) and the flea borne strains of endemic typhus began to attract attention (after 1926) that there was a beginning laid for a typhus-spotted fever group.¹⁵⁰ The more recently widened knowledge of the mite borne group⁵⁴ of spotted fevers has so added to the group that it now seems possible to reconstruct the literature of the past twenty-five years into something like a systematic whole.

Although several of the diseases of the group have a clinical history extending back many years, it must be remembered that almost nothing was known concerning their mode of transmission, bacteriology, or immunology until very recent years, and that the conception of a spotted fever group did not begin to take scientific form until about seven years ago when the so-

called rickettsial group of diseases (typhus fever and Rocky Mountain spotted fever) began to be broached.¹⁵⁵ Since then, findings in the tsutsugamushi subgroup have definitely placed it among the fevers having rickettsial bodies as characteristic or almost characteristic elements in their histopathology.⁵⁰

For the purpose of forming a brief chronology, the chief discoveries that have served to establish the typhus-spotted fever group are given below. Only with regard to the more important discoveries can we take notice here.

GEOGRAPHIC DISTRIBUTION

Until a decade or two ago typhus fever was thought of only, or at least principally, in connection with the colder latitudes of the globe, it having been said not to exist in the tropics. This generalization is substantially correct for Old World typhus and for its variant, tabardillo of Mexico and the Andes. It is now known, however, that the governing consideration in the distribution of classical typhus is the climatic factor that conditions the survival of body lice,³ this factor being the absence of protracted, extreme heat. Against the flea borne endemic typhus, extreme heat is not a barrier, hence endemic typhus can occur wherever the flea (particularly the rat flea) is found. As fleas have an almost world wide distribution, being actually more common in the warmer temperate and torrid zones, endemic typhus is potentially almost cosmopolitan, with slight varietal differences being recognizable according to locality. These slight differences of strain are, however, almost entirely of serologic character, clinical

TABLE I

Chronology of Discoveries in the Typhus-Spotted Fever Group

TYPHUS FEVER SUBGROUP (LOUSE BORNE AND FLEA BORNE)	SPOTTED FEVER SUBGROUP (TICK BORNE)	TSUTSUGAMUSHI SUBGROUP (MITE BORNE)
1908 Yersin and Vassal transmitted typhus from man to man by blood inoculation, and expressed opinion typhus was transmitted by insect bites	1902 Wilson and Chowning report on malignant type of Rocky Mountain spotted fever, and suspect ticks as vectors	1907 Tanaka showed that the blood of a man ill with tsutsugamushi disease is infectious
1909 Typhus transmitted from man to man by body lice (Nicolle, Compte and Conseil)	1906 Ricketts demonstrates presence in nature of ticks infected with spotted fever, and hereditary passage of virus through eggs	1908 Yersin described clinically a typhus-like disease from Cochin China
1910 Endemic typhus of eastern U S described by Brill as distinct disease	1908 Tick transmission of Rocky Mountain spotted fever to man reported by McCalla and Brereton	1910 Lymphatic pseudo-typhus (Mossman fever) described clinically by Smithson
1910 Tabardillo and Rocky Mountain spotted fever shown to be different diseases (Ricketts and Wilder)	1909 From Rocky Mountain spotted fever material Ricketts describes intracellular organisms later known as rickettsia bodies in his honor	
1910 Tabardillo virus shown to be nonfilterable by Ricketts and Wilder, described as bodies like ones found by Ricketts in spotted fever	1910 (See under typhus)	
1912 Anderson and Goldberger identify Brill's disease and tabardillo as being varieties of same disease	1910 Fievre boutonneuse described from Tunis by Conor and Bruch	1912 Tidswell reports on Mossman fever
1914 Sergeant, Foley and Vialette describe rickettsia found only in lice collected from typhus cases	1911 Pathologic anatomy of Rocky Mountain fever described by LeCount	1913 Mossman fever studied by Clark
1915 Trench fever described by Graham	1911 Tick-bite fever of Africa described clinically by McNaught	1914 Breinl, Priestley and Fielding report on Mossman fever
1916 Immune serum against typhus, fairly effective for laboratory animals, developed by Nicolle and Blazot	1916 Wolbach describes <i>Deimacentrorenus rickettsi</i> a rickettsial organism, as pathogen of Rocky Mountain spotted fever	1914 Pseudo-typhus of Deli Sumatra described clinically by Schuffner, ticks being suspected as vectors
1916 DeRocha-Lima describes <i>R. prowaseki</i> as found in typhus transmitting lice, but never in typhus free lice and considers it pathogen of typhus fever		1915 Dowden gives brief clinical description of scrub typhus of Malaya
1916 Toepfer finds rickettsia in trench fever lice and associated them etiologically with the fever	1917 Tick typhus described clinically from northern India by Megaw	1917 Tsutsugamushi disease transmitted to monkeys by larval mites (Miyajima)
1917 Weil and Felix introduce the <i>Proteus X₁₉</i> agglutination test for typhus fever		

TABLE I (Continued)

TYPHUS FEVER SUBGROUP (LOUSE BORNE AND TLLA BORNE)	SPOTTED FEVER SUBGROUP (TICK BORNE)	TSUTSUGAMUSHI SUBGROUP (MITT BORNE)
1917 Neill describes scrotal lesion of tabardillo in guinea pigs		
1918 Brill's strain of endemic typhus recognized in western Europe by Netter and Blaizot	1920 Carducci and Falcone independently describe fièvre boutonneuse in Italy as special form of eruptive fever	1920 J A Mitchell describes mild typhus-like disease in Transkei, South Africa
1918 Proteus X-strains demonstrated not to be pathogen of typhus fever nor to immunized laboratory animals against the disease	1921 Inuga fever described from Portuguese East Africa by Kudicke, ticks being incriminated on clinical evidence	
1919 Pathology of typhus described by Grzywo-Dabrowsky (1918) and by Ceelen	1923 Rocky Mountain spotted fever organism grown in tissue culture (see under typhus subgroup)	1923 Prates in Lourenço Marques describes typhus-like disease with primary ulcers
1919 Bradford, Bashford and Wilson claim to have cultivated the rickettsial organisms of typhus and of trench fever	1923 Noguchi finds three strains of rickettsiae from spotted fever ticks to be non-pathogenic	1923 Cowdry reports on distribution of rickettsiae in tissues of insects and arachnids
1919 Two commissions — English War Office, and American Commission study trench fever	1924 Spencer and Parker recognize phases of latency and activity of spotted fever virus in ticks, and report on virus in blood	
1919 Typhus caused by <i>R. prowazeki</i> , and trench fever by <i>R. quintana</i> , according to Arkwright, Bacot and Duncan	1925 Balfour, Clearkin, Anderson and Clark redescribe typhus-like fever of South Africa, and incriminate ticks as vectors	1926 Nagayo describes a rickettsia as cause of tsutsugamushi disease
1922 Endemic typhus in Australia described by Hone	1925 Guacarapa spotted fever of Venezuela described clinically by Garcia	
1923 Wolbach and Schlesinger report cultivation of organisms of typhus and of spotted fever in tissue and plasma cultures	1927 Fièvre boutonneuse recognized on French littoral by Olmer, and by Boinet and Pieri, insect transmission being suspected	1927 Frill at Potchestroom, South Africa, describes a typhus-like disease
1926 Kuczynski and co-workers publish biological and pathogenetic studies on rickettsiae in typhus and Rocky Mountain spotted fever	1927 Spencer and Parker develop a spotted fever vaccine prophylactically effective for man	1928 Tsutsugamushi virus cultivated in testicle of living rabbit by Ogata and by Ishiwara
1926 Endemic typhus in southern portion of U S described by Maxcy, who incriminates fleas as vectors	1928 Cooley reports on tick parasites	
1930 Mooser and Dummer find rickettsia in tunica vaginalis of guinea pigs infected with endemic typhus	1930 Fièvre boutonneuse shown to be tick borne by Durand and Conseil	1930 Scrub typhus of Malasia studied immunologically and clinically by Fletcher
	1930 African tick-bite fever transmitted to guinea pigs by Pijper and Dau	1930 Marcandier and Bidreau study ship typhus and incriminate a rat acarid as the possible vector

TABLE I (Continued)

TYPHUS FEVER SUBGROUP (LOUSE BORNE AND FLEA BORNE)	SPOTTED FEVER SUBGROUP (TICK BORNE)	TSUTSUGAMUSHI SUBGROUP (MITE BORNE)
1931 São Paulo strain of endemic typhus described by Piza, DaRocha-Lima and associates	1930 Rickettsia described in skin lesions of fièvre boutonneuse by Durand, Kuczynski and Hohenadel	1930 Lewthraite reports on epidemiology of scrub typhus of Malasia
1931 Mooser, Casteneda and Zinsser demonstrate endemic typhus reservoir in wild rats	1931 Rocky Mountain spotted fever found to be in southeastern U S endemic area by Badger, Dyer and Rumreich	1931 Wolff reports on immunology of pseudo-typhus of Sumatra
1931 Pinkerton and Maxcy describe anatomical pathology of endemic typhus in man, with <i>R. prowazeki</i> in vascular lesions of human brain	1931 American Mountain tick-fever recognized as entity distinct from Rocky Mountain spotted fever by Toomey	1931 Marcandier and associates demonstrate absence of cross immunity between ship typhus and fièvre boutonneuse
1931 Nagayo cultivates typhus organism in living rabbit eyes (see under tsutsugamushi disease)	1931 Fièvre boutonneuse immunologically distinguished from ship typhus by Marcandier, etc	1931 Nagayo and associates describe rickettsiae from typhus and tsutsugamushi in tissue cultures, with use of eyes of living rabbits as culture medium
	1932 Virus of fièvre boutonneuse stated to be filterable by Blanc and Caminopetros	1931 Dove and Shelmire draw attention to tropical rat mites as possible vectors of endemic typhus

differences being wanting, trifling or inconstant

As to the tick borne typhus-like fevers there is a somewhat more striking geographic correlation than with the louse or flea borne diseases. Within the tick borne subgroup we are brought to recognize the more limited distribution of ticks, not perhaps as a class, but as to the actual species that are vectors of the tick borne typhus-like spotted fever, or fevers. Here we observe the highly localized character of certain tick borne fevers, the localization often being correlatable with certain definite mountain slopes and the adjacent wooded waste lands. Two, at least, of the tick borne typhus-like fevers, spotted fever of the Rocky Mountains and fièvre boutonneuse of the Mediterranean, have in recent years apparently spread over an area wider than their original habitat. Of the other fevers of this subgroup not

enough is known to be able to state to what extent their distribution is limited, or will be kept in check by conditioning factors peculiar to their present habitat.

Concerning the mite borne diseases we have to note the very interesting fact that they are positively known up to the present time only in that portion of the world embracing eastern Asia, Malasia and the adjacent portion of Australia. A possible exception is ship typhus which has been suspected, but not proved, to be transmitted by the tropical rat mite, *Liponyssus bacoti*, Hirst^{67, 68}. A possible case of tsutsugamushi disease occurring in the mandated territory of New Guinea was described by Sinclair in 1930⁶⁹.

CLINIQUE AND COMPARATIVE SYMPTOMATOLOGY

The nosography of the typhus-spotted fever group, up to very recently

has rested almost solely on a clinical basis for want of sufficient data concerning the bacteriology, immunology and anatomical pathology of the various members of the group. Serologic-immunologic studies have, however, within the past five years, and particularly within the past two years, contributed to a more exact knowledge of the relationships of these diseases. The three most significant results of these immune serum studies have been to show that (1) Those diseases clinically recognizable as dissimilar, are actually so from the standpoint of being different pathogenic entities, (2) that so far, at least, the prime division of the group according to the biologic order of the insect vectors concerned is a valid mode of classification, and (3) that for each disease one or more varietal strains can be made out serologically, without an always correlatable disparity in clinical course, appearance or duration.

The comparative symptomatology of the diseases that comprise the typhus-spotted fever group can best be interpreted by considering the lymph-blood-vascular (particularly the lymph system) and the cutaneous reactions to these diseases. Prostration (often severe, and with coma), rheumatoid pains (often severe), and a tendency to muscular spasticity are almost constant phenomena in varying degrees, but they do not afford as objectively differentiating evidence for classification as do the lymph-blood-vascular and cutaneous reactions. In fact it may be said that as far as is now known, the anatomical pathology of the typhus-spotted fever group is primarily and almost exclusively limited to the circu-

latory system, particularly the lymphatics and the smaller and smallest blood vessels. Dry bronchial inflammation and cerebral toxic manifestations occur in the most severe fevers of this group, but they are rather consequential than primary lesions.

The comparative symptomatology of the diseases of the typhus-spotted fever group can be correlated in a general way with the vectors implicated, thus a primary lesion at point of inoculation is not observable in the louse borne and flea borne diseases, is observable in some but not all of the tick borne diseases, and is virtually a constant phenomenon in the mite borne diseases. Secondary regional lymphangitis and lymphadenopathy is not a part of the louse and flea borne diseases, is absent, inconstant, or not well developed in the tick borne diseases, but is distinctly a characteristic of the mite borne group of fevers. While the latter show both a primary lesion and a regional lymphangitis-lymphadenopathy, it should be noted that the two are not constant accompaniments of one another, the tsutsugamushi disease and scrub typhus of Malasia having a practically constant primary patch but a less determined lymphadenitis, whereas the pseudo-typhus of Sumatra and lymphatic pseudo-typhus (Mossman fever) of Queensland have a constant and well marked disposition to lymphadenopathy, but with a less well accentuated primary sore than in tsutsugamushi disease and scrub typhus of Malasia.

In regard to the cutaneous lesions of this group one must remark a strong family resemblance, particularly within each subgroup. Thus the manner of appearance and distribution of rash can

not be invoked as a clearcut, dependable basis for differentiation. Despite individual variations and a strong family resemblance, there can, however, be made out certain broad distinctions even between diseases of the same subgroup. Thus, in the louse and flea borne subgroup one remarks the rash of tabardillo to be usually less papular, larger and distributed more on the lower part of the body than in classical typhus. Endemic typhus, which on the whole is milder than classical typhus (although exceptions occur), has as a rule a somewhat smaller lenticular lesion with a lesser tendency to become petechial, it may be, but usually is not, quite as profuse as in classical typhus, and is not as commonly accompanied by a diffuse scarlatinoid (reticular) blush. Within the tick borne group one finds in Rocky Mountain spotted fever that the rash (accompanied by a diffuse cyanotic blush in severe cases) shows marked passive congestion, and appears on the wrists and ankles, spreading upwards as edematous but compressible macules that usually spare the face. In *fièvre boutonneuse* the rash is much more papular (infiltrated) than in spotted fever, appears first on the face or upper part of the trunk, is larger, more sparsely set, and of longer duration considering the comparative intensity and duration of the two fevers. Kumaun tick typhus has characteristics of both Rocky Mountain spotted fever and *fièvre boutonneuse*, but more closely resembles the latter. Tick-bite fever of South Africa resembles somewhat the *fièvre boutonneuse* but also has some of the features of the mite borne diseases. Within the mite borne subgroup the rash is approximately the

same in all the clinical types, but tends to be less pronounced in scrub typhus and pseudo-typhus of Sumatra than in Japanese flood fever. In lymphatic pseudo-typhus the rash has a vesicular tendency.

Respecting the incubation period, mode of onset, duration, severity of muscular pains and intensity of prostration there are equally as wide or wider variations than among the circulatory and cutaneous lesions. Thus we find a shorter incubation period in the louse and flea borne subgroup than in some of the tick borne diseases, and a still longer incubation period in one (or sometimes two) of the mite borne diseases. The mode of onset and severity of muscular pains are roughly correlatable with the ultimate severity of the disease, but even here we find that tsutsugamushi disease develops intense prostration at a somewhat slower rate than the malignant forms of the louse borne and tick borne fevers.

Toxemic symptoms as manifested by cerebral disturbances and circulatory collapse may occur in any of the severer fevers of the typhus-spotted fever group, but they are rare in some, average in others and well nigh constantly fatal in others. Thus the mortality rate differs greatly within the group, but rather according to the type of the disease under consideration than for the disease as a whole, a matter particularly well exemplified by spotted fever of the Rocky Mountains, certain epidemics of typhus fever, and occasionally by Japanese-Korean flood fever. Nor can it be said that there is great disparity in the mortality among the three great subgroups, each

having grave as well as mild diseases, but of the three the mite borne are collectively both somewhat less fatal and less of a world problem than the tick borne, flea borne, or louse borne diseases

The comparative semeiology of the several diseases, and their more distinctive varieties, are briefly summa-

rized in the accompanying table (see table II) For a fuller description of the tick borne diseases see a subsequent article entitled "The Tick Borne Typhus-like Fevers".

BACTERIOLOGY

In common with practically all diseases of a zymotic character, typhus

TABLE II

LOUSE AND FLEA BORNE	SEASONAL	INCUBATION PERIOD	MODE OF ONSET	PRIMARY SORE	RASH
OLD WORLD TYPHUS	Winter chiefly, or any time	10 to 14 days Mostly 12	Abrupt with rigors, headache, myositis	No	3d to 5th day, Subcuticular, and petechial papules
ENDEMIC TYPHUS	Spring to early Fall	10 to 14 days	Subabrupt or abrupt, like mild typhus	No	Frequently but not commonly petechial
TRENCH FEVER	Any time, winter chiefly	6 to 8 days, may be 30 days after exposure	Sudden with giddiness, dyspnea	No	Delicate small, red macules on chest, abdomen
TICK BORNE					
ROCKY MOUNTAIN SPOTTED FEVER MALIGNANT TYPE	Early spring to mid-summer	5 to 10 days mostly 7	Abrupt with dull headache, conjunctivitis, vomiting and severe rheumatoid pains	No	Appears 3d or 4th day as red macules on ankles and wrists, spreads upwards becoming cyanotic-petechial
MILD TYPE	Early spring to mid-summer	7 to 10 days	Fairly abrupt rheumatoid pains, etc	No	3rd to 5th day spreads upwards, cyanotic-petechial
BENIGN RICKETTSIAL DISEASE*	Late spring and summer	10 to 14 days mostly 12	Sudden with headache, chilliness, nausea	No	Very rare, somewhat like mild R M S F
AMERICAN MOUNTAIN TICK-FEVER	Early spring to September	3 to 7 days mostly 4	Sudden with headache, chilliness, bone pains, nausea	Often Yes	No
FIEVRE BOUTONNEUSE	Only in late spring and summer	5 to 15 days mostly 8	Fairly abrupt rheumatoid pains	Yes but not always	Large hard papules on 3rd day, on face thence downward, palmar and plantar lesions, hemorrhagic tendency slight

(also tsutsugamushi disease) was early the subject of numerous bacteriological investigations made according to the methods available during the first decades of bacteriology. Numerous were the organisms found in, and at times identified etiologically with typhus material. For our purpose, however, it would serve no useful end to review

the early reports on the bacteriology of these diseases, as now the reports have only historical interest. While some of the early workers may have observed organisms of rickettsial character, they failed to bring forth proof of an etiologic relationship of these minute bodies to the diseases in which they were encountered. Even in spotted

TABLE II (Continued)

COMA	DURATION OF FEVER	MODE OF TERMINATION	CON-VALESCENCE	IMMUNITY	MORTALITY
Very frequent, early	10 to 18 days mostly 14 days	Crisis or abrupt lysis	Usually rapid, occasionally with relapses	Absolute	12 to 40 per cent, Average 19%
Frequent, often transitory	12 to 15 days	Abrupt lysis	Rapid and without relapses	Relatively absolute	5 to 12 per cent
No	35 to 42 days occasionally 5 to 9 days, relapsing	Gradual lysis	Moderately rapid	No	0
Almost invariable early, profound	Usually fatal 5th to 9th day (average 7th day) Survivals run 21 to 26 days	Subabrupt lysis	Slow, occasional relapses, gangrenous sequelae	Absolute	85%
Mild, very occasional	21 to 28 days	Lysis	Fairly rapid, frequently slow	Considerable but for mild type only	4 to 20% Average 15%
No	5 or 6 days followed by one-day remission	Rapid lysis	Rapid	?	0 ?
Light stupor and delirium	2 or 3 days followed by one or more irregular remissions	Lysis, usually rapid	Usually fairly rapid	?	About 0.5%
No	12 to 17 days mostly 14 days	Lysis	Moderate in young, gradual in elderly	Moderate transitory	Under 1%

TABLE II (Continued)

LOUSE AND FLICA BORNE	SEASONAL	INCUBATION PERIOD	MODE OF ONSET	PRIMARY SORE	RASH
KUMAUN TICK TYPHUS	Late spring and early summer	14 to 21 days	Gradual	Yes	Profuse, ap- pears 5th day on upper trunk, pe- techial by 8th day
INUGA FEVER	?	?	Sudden with chills, head- ache, con- junctivitis	Yes	Pea sized, red- dish morbilliform macules Begins 1st day, developed by 5th
GUACARAPA FEVER	?	?	Similar to Rocky Moun- tain spotted fever	No ?	Closely resembles Rocky Mountain spotted fever
TICK-BITE FEVER OF NATAL	Probably in only spring and summer	8 to 10 ? days	Sudden with severe head- ache	Yes	Profuse dark red morbilliform, on 3rd to 6th day
RHODESIAN FEVER*	Summer and autumn	?	Suddenly with shivering and headache	Yes	4th or 5th day universal maculo-papular non-petechial
PORT ELIZA- BETH FEVER*	February to July	?	Sudden or subabrupt; headache	No	In 50% only, sparse macules
MITE BORNE					
JAPANESE FLOOD FEVER	Middle of July to October	4 to 10 days	Rapid with rigors, front- al headache	Yes	5th to 7th day as papules, spreads downwards chiefly as macules on body
SCRUB TYPHUS OF MALASIA	No	11 to 21 days	Abrupt shivering headache	No	4th to 6th day, maculopapular on chest, ab- domen
PSEUDO- TYPHUS OF SUMATRA	June to Aug Nov to Jan	12 to 16 days	Rapid	Yes	Roseolar, univer- sal, but mostly on trunk and flanks Fades slowly, sometimes hemor- rhagic
LYMPHATIC PSEUDO- TYPHUS	?	6 to 10 days	Sudden or gradual	Yes but not always	Macular or ves- icular
SHIP TYPHUS	Any time mostly summer	About 10 days	Sudden but usually mild	No	Resembles mild endemic typhus
EX-REDU- VIIDAE					
REDUVID SCARLA- TINOSIS	Summer June and July	5 to 7 days	Fairly abrupt initial symp- toms mild	Yes not well marked	Macular exuda- tive, scarlatinoid face-limbs chiefly

*Vector uncertain

TABLE II (Continued)

COMA	DURATION OF FEVER	MODE OF TERMINATION	CON-VALESCENCE	IMMUNITY	MORTALITY
?	10 to 14 days mostly 12 days Paratyphoid type	Lysis	Rapid	?	5 to 10 per cent
Exceptional	7 to 10 days	Crisis or rapid lysis	Rapid	?	0 ?
?	Usually fatal 7th to 9th day	Crisis or lysis	Rapid	?	High
?	8 to 11 days	Rapid lysis	?	?	0 ?
Light stupor, delirium	10 to 14 days 2d rise after eruption	More or less rapid lysis	Usually rapid without sequelae	?	About 7%
No	8 to 14 days, low, irregular, occasionally high	Rapid lysis	Rapid	?	0 ?
Frequently, late	20 days	Lysis	Usually quick	Very considerable, somewhat transitory	30%
Yes, or delirium in even mildest cases	fever may be low, 14 days	Lysis	Moderate broncho-pneumonia common sequel	Lasting	4 to 14 75% Average 6 75%
Frequent, or delirium	11 to 15 days, typhoidal with nervous symptoms	Lysis	Fairly rapid Pulmonary complications	Yes	6 to 8%
No ?	3 to 21 days	Lysis	?	Slight	Under 1%
Very exceptional	8 to 12 days	Rapid lysis	Rapid	Moderate	1 to 2%
May occur	7 to 21 days mostly 10	Rapid lysis	Slow	?	Probably 3 to 5%

fever Anderson probably anticipated Ricketts in observing the minute microgametic life that is causal of spotted fever, but he did not carry his observations to a practical conclusion.

Howard Taylor Ricketts in 1909 described minute intracellular organisms in spotted fever material, referring to them as bodies that could be associated not only with spotted fever but also with the known vector of the disease, the tick *Dermacentor andersoni*, and transmitted through the eggs of the latter from one generation to another.⁹² A year later, working with typhus fever material in Mexico, Ricketts observed in typhus infected lice and in typhus material, intracellular organisms of a character similar to the bodies he had described in connection with spotted fever of the Rocky Mountains.⁵ Unfortunately his untimely death from typhus fever closed for him one of his major investigations. However his work was taken up by Hegler and von Prowazek¹⁸ in connection with typhus, and by S. Burt Wolbach in connection with spotted fever of the Rocky Mountains.¹⁰⁷ Von Prowazek, likewise dying of typhus fever, did not live to complete his studies, it becoming the good fortune of Sergeant, Foley and Vialette, in 1914, to describe rickettsia peculiar solely to lice known to be venenous with typhus fever.¹⁸ They, however, cautiously refrained from claiming a proven etiogenic relationship for these organisms. Two years later DeRocha-Lima confirmed these observations and claimed an etiologic rôle for the organism, which he named *Rickettsia prowazeki*.¹⁵ Subsequent studies made with a louse, *Pediculus longiceps*, and *Macacus rhe-*

sus monkeys enabled Arkwright, Bacot and Duncan, in 1919, to state that the etiologic rôle of *R. prowazeki* for typhus was so circumstantial as to be all but proven, as the lice they were working with, normally not carriers of rickettsia, became infected with *R. prowazeki* when allowed to feed on monkeys suffering with typhus fever.¹² Weigl in the meantime having introduced the ingenious method of feeding lice by anus,¹⁴ Atkin and Bacot, in 1922, proved that *R. prowazeki* developed in *Pediculus longiceps* after feeding on typhus infected monkeys and after rectal injections of blood from typhus cases, thereafter being able to cause typhus fever in monkeys.⁴¹ The method of Weigl, employed by Atkins and Bacot, was equivalent to the living culture medium method defended by Wolbach in 1925.¹⁵⁶ Since the equivalent fulfillment of Koch's postulates by Atkins and Bacot, numerous studies have been carried out on *R. prowazeki*, the chief ones being by Weigl, Wolbach and Schlesinger, Kuczyński and his coworkers,⁴³ and more recently those by Nagayo in the eye of the living guinea pig,⁷¹ and by Nigg and Landsteiner in tissue culture.⁸³

Whether or not the organism recovered from active typhus fever cases by Plotz, Olitzky and Baehr,^{14,23} is an anaerobically cultivatable form of *R. prowazeki* has never been definitely established, but the present weight of evidence is against such a supposition.⁸⁰

Weil, in 1915, noted a fairly constant non-saprophytic occurrence of yet another organism, a *Proteus* bacillus (two strains, X₁ and X₂) in con-

nection with active typhus fever cases. Although these strains of *Proteus* were agglutinated by high dilutions of sera from cases of typhus fever during the fastigium, it was early proved that neither strain was capable of producing typhus fever in non-immune laboratory animals or in man. Also it was shown by Landsteiner and Hausmann,²⁹ by Dorr and Pick,³⁰ and by Möllers and Wolff,³¹ to be incapable of immunizing susceptible laboratory animals against typhus fever. Thus the rôle of the *Proteus X* strains to typhus fever was early recognized as being of unknown character despite the fact that Dienes²⁸ recovered these organisms from the blood of typhus fever patients in 30 per cent of the cases which he examined. This relationship of *Proteus X* strains to typhus fever has not been clarified to date although Schultz³⁶ and others have expressed the opinion that the body louse can and probably does more or less frequently inoculate man with other organisms simultaneously with the rickettsial infection.

This brief résumé of the virus studies on typhus fever will be closed by noting that a negative phase of the problem has been set forth by Brumpt, by Weigl, by Noguchi and others, who have shown that non-pathogenic rickettsias also occur in lice as in other arthropods. These non-(typhus) pathogenic rickettsias of lice are for the present grouped under the name of *R. pediculi*, and are believed to be identical with *R. quintana* and *R. wolhynica*, the trench fever rickettsias of the body louse. In regard to the other extracellular rickettsias from mallophaga, etc., Wolbach states that there is very

little if any reason for regarding them as different from familiar bacteria. These organisms have been cultivated on blood agar media by Noller in 1917,¹⁷ and by Sikora in 1921.³⁴

Spotted fever of the Rocky Mountains was the second typhus-like disease to be more conclusively associated with rickettsia. This was accomplished by Wolbach,¹⁰⁷ and by Wolbach and Schlesinger,¹²⁷ by pathological studies, by comparative tick studies, and by proving tissue-plasma cultures of the organism to be virulent for spotted fever.¹¹³ The organism has also been cultivated (?) by Kuczynski and by Otto and has been found in spotted fever rabbit material by Connor,¹⁴⁰ by Nicholson,¹²⁰ and by Reimann.¹⁵¹ Subsequent work on the virus has been by Spencer¹³⁸ and Parker,¹⁵⁸ who have however, confined themselves to the immunological aspects of the virus.

Trench fever was the third rickettsial disease to be placed on a reasonably acceptable bacteriological basis.²⁴ This was accomplished by Bacot³⁷ in 1921 despite the previous report of the American Trench Fever Commission which held to a filterable virus as the cause of trench fever.²⁶ Bacot's observations, however, await confirmation.

Nagayo in 1926 was the first to state that tsutsugamushi disease was caused by an organism referable to the rickettsial group. Subsequent tissue culture studies by Ishiwara and Ogata,¹¹ employing the living rabbit testicle, and by Nagayo⁵⁹ employing the living rabbit eye have established the etiologic relationship of the organism which has been named *R. orientalis*. Nagayo, 1926.

As to *fièvre boutonneuse* (exanthematic fever) P. Durand, Kuczynski, and Hohenadel stated in 1930 that they observed rickettsia bodies in the cutaneous macules of the disease in man. Georges Blanc and J. Caminopetros reported, however, in 1932, that the virus of *fièvre boutonneuse* is filterable through the Chamberland candle L.

The other diseases of the typhus-spotted fever group, namely Kumaun Tick Typhus, Tick-bite Fever of Natal, Inuga Fever, Guacarapa Fever, Scrub Typhus of Malasia, Pseudo-typhus of Sumatra, Lymphatic Pseudo-typhus of Queensland, Port Elizabeth Fever, Ross's Rhodesian Fever, Ship Typhus, and Reduviid Scarletosis, have an unknown bacteriologic status.

The rickettsial origin of endemic typhus has been recently more conclusively demonstrated by Mooser and Dummer, who, in 1930, found rickettsia in the tunica vaginalis of guinea pigs infected with endemic typhus,⁶⁸ and by Pinkerton and Maxcy who found *R. prowazeki* in vascular lesions in the brain of a man dead of endemic typhus (or spotted fever, eastern type).⁸²

IMMUNOLOGY

Apart from considerations resting upon the morphologic and cultural characteristics of the minute intracellular organisms so definitely associated with the rickettsial group of diseases, there has been woven an extremely interesting and important web of evidence consisting of the serologic reactions constantly proper, and more or less differentiating, to each of the diseases (or at least subgroups) of the typhus-spotted fever group. In fact

it is immunological rather than bacteriological evidence that confirms clinical evidence in the case of several of the tick borne typhus-like fevers.

The immunologic studies that have been made in this group, for diagnostic purposes, may be divided into animal inoculations (cross immunity tests) and bacterial agglutination reactions. The immunologic studies for prophylactic^{16,47,53} and therapeutic purposes^{16,21} have so far had to do only with typhus fever, and spotted fever of the Rocky Mountains. A potent therapeutic serum or vaccine, available for man, has not yet been developed for any disease of this group. Prophylactically, however, the chemically attenuated virus vaccine for spotted fever of the Rocky Mountains, as developed by Spencer and Parker, is of great value, and has recently been discussed at length by the author.²⁸³

The cross immunity tests, utilizing guinea pigs chiefly, has been applied to distinguishing Rocky Mountain spotted fever from classical typhus fever,⁶⁴ endemic typhus, and tsutsugamushi disease, and in distinguishing classical typhus and endemic typhus from *fièvre boutonneuse*.

The agglutination tests depend upon furtherance of the observations of Weil and Felix²⁵ that typhus serum agglutinates in high dilution a strain of proteus bacillus denominated *Proteus X₁₀* (a variant of which is also referred to as the Warsaw strain). This, the Weil-Felix test, has been extensively applied to all, or almost all of the diseases of the typhus-spotted fever group. It has been found strongly positive in some of the diseases (classical typhus, tabardillo, Brill's

disease, ship typhus of Malasia, and ship typhus of Toulon), moderately positive in others (Rocky Mountain spotted fever, fièvre boutonneuse, "typhus" in Kenya, and occasionally but rarely in Kumaun tick-typhus of India), and absent in still others (tsutsugamushi disease, scrub typhus of Malasia,^{61,63,65,66} and pseudo-typhus of Sumatra^{73,74}) it is observable that agglutination occurs against a non-indologenic strain of proteus called *Proteus* X₂, or the Kingsbury strain. Some authors have proposed to classify all of the fevers of the typhus-spotted fever group into two divisions on the basis of their reaction to the Warsaw or the Kingsbury strain, but such a classification seems to us to rest on too narrow a basis.

Ross in Rhodesia has recently described a fever of the fièvre boutonneuse type that is negative for both the Warsaw and the Kingsbury strains.⁶⁹

PATHOLOGY

The morbid anatomy and histopathology of the first known disease of this group were completely worked out, according to the older standards, prior to 1910. Modern refinements of technic have, however, served to add somewhat to the pathological descriptions that had given the older known diseases a universally recognized place in general medical literature. Thus for spotted fever of the Rocky Mountains we may note the pathological studies of LeCount,⁷⁷ of Wolbach,¹¹⁹ of Reimann,¹⁸¹ and of Lillie.²²⁶ For newer additions to the histopathology of typhus fever we are chiefly indebted to Grzywo-Dabrowsky, Ceelen, Wol-

bach, Todd and Palfrey,⁴⁰ and to Da-Rocha-Lima and Montero,⁷⁸ with related work by Zinsser, Mooser, Dummer and Castaneda.^{68,80,86} The pathology described by Pinkerton and Maxcy⁸² was very probably not that of typhus but of Rocky Mountain spotted fever—eastern type.²²⁶ The older work on typhus, with additions of their own observations, was reviewed by W. Grzywo-Dabrowsky in Virchow's Archiv (ccxv, 229) for 1918, and by W. Ceelen in 1919 (Ergebn der allg Path u path Anat, xix, 1 Abt, 307).

As tsutsugamushi disease had for long been quite actively studied by opposing groups of Japanese investigators, the usual groundwork of its pathology had become well covered prior to 1925. With the introduction of the newer concepts relating to the typhus and spotted fevers, they were, by analogy, applied quickly to the study of tsutsugamushi disease by Nagayo, by Ogata and Ishiwara, and others. Their studies have not only abundantly demonstrated the rickettsial element of the disease but have served to introduce ocular and testicular inoculations as useful methods for cultivating and studying the morphology of the virus.

With regard to the newer and lesser known diseases we have to note that with respect to scarcely a one has there been an adequate beginning in the study of their morbid anatomy and histopathology. Limited exceptions may be noted with respect to fièvre boutonneuse (in which Duran and Kuczyński and Hohenadel have recently carried out some histopathological studies) and with endemic typhus—particularly the São Paulo strain and

the strain of the southern United States^{76,78}

The lack, or virtual lack of mortality in several of the less well known diseases, and the isolating circumstances attending their locality of occurrence, have undoubtedly served to restrict the opportunities for obtaining pathological material from these diseases

Zinsser, Mooser and Castanada⁸⁰ have recently suggested the possible primitive unity of the diseases of this group

In concluding this nosologic synthesis it should again be emphasized that lack of sufficient knowledge of the lesser known diseases renders it impossible to more than approximately indicate relationship at this time. Thus, while not attempting to predict, it is warrantable to surmise that muga fever and tick-bite fever of Natal (Pretorian ten day fever) may be one and the same disease. Likewise it may be shown that Kumaun tick-typhus of India may be merely a varietal strain of *fièvre boutonneuse*. It does seem, indeed, that Schuffner's pseudo-typhus of Sumatra is merely a clinical type of Japanese-Korean flood fever, and does not deserve to be catagoried as a separate entity. Before such problems can

be solved, the clinical analysis of much larger series of the lesser known diseases will need to be made equally as well as a study of the related bacteriological and immune serum reactions. Even as to the range of vectors concerned there is much uncertainty. For example, it is possible that tick-bite fever of Natal may be transmitted by mites as well as ticks, or possibly by mites alone. And as to the vector of scrub typhus of Malasia, the acarid nature of its vector is known only as a strong possibility rather than as a certainty. Also, from unpublished observations of the author it seems that other arthropods than those mentioned are capable of inoculating man with disease of rickettsial nature. Thus a sufficiently full knowledge of the typhus-spotted fever group will not be gained until time has afforded an opportunity for correlating an abundance of observations such as those recently made by Garcia for guacarapa fever, by LaBier,¹⁵⁴ by Spencer (mentioned by Parker¹⁸⁷), by Kemp,²²³ by Toomey,²⁸⁰ and by Reimann²⁸¹ for spotted fever, and of the Italian and Greek observers concerning *fièvre boutonneuse* in the Mediterranean countries of the East

The Modern Hospital—Its Relationship to the Physician

By BENJAMIN W. BLACK, M.D., F.A.C.P., *Oakland, California*

THE Modern Hospital is the handmaiden of scientific medicine. It is the laboratory in which medical science is advanced and medical art perfected. In no other place have those facilities been so well assembled by which practitioners of modern medicine are able to give the patient efficient and satisfactory care. The public has learned to regard hospitals as places of hope and amelioration and to have confidence in them.

The number of hospital beds has increased several fold in the past generation in this country. The public attitude towards the care of illness in hospitals has changed during this period so that it is now unusual for patients to be cared for in any other place, even when suffering with but minor complaints. There are more than seven thousand hospitals in the United States and in them are employed six hundred fifty thousand persons who care for twelve million patients each year. With their vast investment in buildings, furnishings, and expensive equipment, hospitals have now taken their place in big business. They were first established for the care of the poor, later they were organized for the care of the rich.

The mutual interest between the hospital and the physician demands from each a more thorough appreciation of the function of the physician and his work in the hospital, and of the hospital in its effort to serve the physician, and through him the patient. Unfortunately, too little attention is given to the numerous intricate problems that enter into the day's effort and too frequently the point of view of the physician and his attitude is not understood by the hospital and the lack of sympathy accorded to the hospital does not always result in the best service to the patient with the least per capita cost. Hospitals have always performed a public service, and contrary to the opinion of many, the income from patients pays but little more than half of the necessary cost. Recently in Philadelphia it was found that fifty-nine per cent of the total hospital income came from patients, seventeen per cent from endowments, four per cent from cash contributions and seventeen per cent from other sources. This is quite typical of hospitals in most cities and it is rare when hospitals do not provide free beds for patients unable to pay. On the theory that the public supports hospitals. Because of this public support there is a feeling that hospitals are public utilities which is accentuated because of the manner of their establishment.

Presented at the San Francisco meeting of the American College of Physicians, April 4, 1932.

In the main, the management of hospitals is in reasonably efficient hands and business-like administration characterizes their management in America. Standardized methods found in factories or automobile plants cannot well be expected. The care of a patient in a hospital still remains a special feature with its individual problems always predominating. Certain administrative principles apply to hospitals as to other business organizations, but because of the special service rendered in each case, no marked degree of standardization may be expected and successful methods used in hotel operations cannot well apply to hospital administration.

The present financial situation is one of the most distressing problems for the future of hospitals. It is my purpose to discuss with you certain items which enter into the daily work in hospitals for the purpose of presenting to your attention and intelligent understanding, some of the statements made in criticism of hospital costs and certain methods which may be inaugurated with the hope of reducing such costs and at the same time maintaining a standard of service demanded by an intelligent public and required by the physician in charge of the patient. There is an average reduction in hospital occupancy to about fifty-eight per cent of capacity with an average of forty-two per cent of the beds remaining unoccupied. This can not mean that we have too many hospital beds, nor that too liberal provisions have been made for the adequate care of the sick. Sooner or later when different conditions prevail, these empty beds will be needed; additional contributions will

make provision for a greater service to be rendered. During these periods of stress, increasing numbers of patients admitted to the hospital, who during normal times were well able to pay, have now found themselves without funds, thus creating a financial hardship on the part of the hospital to meet the cost of an essential service which cannot be eliminated. Patients, too, that were able to pay liberally for such service under different conditions now turn a most critical eye to any per capita cost which increases their hospital bill.

Industry rearranges its budget when production is curtailed and unemployment results. Curtailment in business followed by unemployment over any prolonged period of time means an increasingly greater amount of illness with increased demands to be expected upon hospital facilities. Hospitals assume an additional burden in order that the budgets in business shall balance, and even in spite of the fact that there is no known *business* reason why hospitals should assume an additional burden, it is safely predicted that they will not shirk their responsibilities towards this humane work even at the expense of great deficits. The public contributes funds for unemployment relief and provides for the victims of famine disaster and expects hospitals to carry increasing burdens at such times as these. Patients cannot be turned away because of lack of funds and the humanitarian traditions together with the support always given the hospital, requires the continuance of such service.

Hospitals are taxed in the state and communities in which they are located, as a general thing throughout this country. They have begged to be re-

lieved from such burdens where relief might be expected. They own real estate and at times receive some revenue from it, they receive endowments, the income of which is used in the main for the relief of the poor, yet there is little response found when efforts are made to have the revision of law to permit hospitals doing charitable work to become tax free. Organized hospitals throughout the country have presented their plea to legislative bodies without any marked material relief found. A much greater service could be expected to the public should this burden be no longer imposed upon them. An enlightened public conversant with these facts may be expected to be friendly to a tax free proposal if supported by those friendly to such a movement. Physicians may be expected to find a new mutual interest because of their increasingly large charitable services, knowing the difficulties confronting the hospitals and the requirements demanded for the same standards of hospital care.

Private practice now requires an investment on the part of the physician to provide a technic in handling the case never before available. This demands for his personal equipment an investment capable of reduction should he make greater use of hospital equipment thereby supplementing his service to patients. The proposal that the hospital shall supply to the practitioner many of the services that he would otherwise have to supply from private investment, is meeting with public approval and promises in its development, mutual advantages to the hospital, to the physician and to the patient. All the facilities in the hospital

ordinarily are used for the sick person demanding bed care, but for the office patient, the physician relies on his office personnel and equipment, or sends such patients to other practitioners or commercial laboratories. Should the hospital become the medical service center in the community, he has available the professional personnel and the scientific apparatus and also has contact with other physicians whose judgment or service he may need. The hospital gains through greater use of its facilities and the patient, it is felt by Dr. Rorem who advocates such a plan, would save time and expense, especially when several consultations and procedures are necessary. Were hospital equipment utilized to a greater extent by the private practitioner, an opportunity for some reduction in cost seems evident and as a rule, the hospital facilities are usually never fully utilized for inpatient care, or they may be readily expanded to absorb a much greater load. In some sections physicians are occupying offices in the hospital or in adjoining buildings with but limited office equipment required, as they utilize the facilities available in the hospital at a great advantage to themselves and to the patient they serve.

Increase in service means an increase in cost, but on the other hand, it means shortened period of hospitalization, better results, and more lives saved. During the past twenty-five years, the average stay of a patient in the hospital has been reduced nearly three fold, while the number of deaths reported are fewer in the same proportion. Whatever can be done to decrease the cost of hospital care has been done and

is being done in numerous ways, but it is unlikely that it is within the power of the hospital itself to reduce this cost to a degree beyond that which may be expected from intelligent, understanding, and full cooperation of all of those who enter into the hospital and its activities. Any hospital administrator may call attention to numerous factors that increase the cost for caring for patients. I would call your attention to certain suggestions that have come to include (a) simpler hospital plans with less expensive construction, (b) the nursing service with proposals for certain changes which are of professional interest; (c) the demand made for expensive equipment and elaborate proposals for research work, and (d) certain opportunities for savings of a minor nature having to do with the professional care of patients.

Expensive institutions require vast sums to operate. Rooms provided for private care are increasingly more elaborate and equipment necessary for efficient service is far beyond that previously supplied. Well-equipped laboratories in charge of highly skilled and expensive personnel must be prepared to do basal metabolic readings, blood chemistry examination, bacteriological, serological, physiological and biological tests as well as numerous others. Patients expect to have a certain amount of necessary service and are willing, when able, to pay for it, but the per capita cost is increased unless due regard is given for the necessity of each service.

It has been proposed that the cost of the needed hospital be reduced by constructing more cheaply with a simpler form of hospital plan. The ten-

dency now is to plan hospitals to include security for patients with studied utility so as to permit reasonably economic administration. Were construction costs reduced some of these admirable features would be lost, and the amount saved but trifling. Could a savings of as much as fifteen hundred dollars per bed be realized that would represent a savings in interest and depreciation of but one hundred eighty dollars per year, and would reflect itself in saving to the patients during a twelve day stay of but about six dollars. This, for reduction of cost to the patient offers little by way of solution.

The nursing service approximates twenty per cent of the total per capita cost and it has been charged that such service to private patients is too expensive. Many feel that the hospital should supply the necessary nursing care, but most hospitals cannot supply the care demanded and live within the income under the present system. Nursing service can no longer depend entirely upon student nurses as was once the case. Schools for nursing are in hospitals because there are patients to be cared for and they can secure this care cheaper by having training schools than they can without. If the maintenance of a training school costs the hospital more than the service of the pupil is worth, the school would no longer be a hospital problem, not because of lack of interest in education, but due to lack of money. Actual training of a student nurse rather than exploitation has been generally accepted as a requirement in the best hospital schools. On the other hand, nurses far in excess of the de-

mand are being graduated each year, many with an education entirely inadequate in competition with those better trained. Hospitals continue to run training schools as a source of profit, unless such is true, the private hospital cannot afford to operate training schools. Nursing educators are seriously applying such methods as may be at their command to eliminate schools with inferior educational standards and to encourage only those schools where training of a high standard may be available to the young woman who matriculates. The same methods are being applied for improving standards of nursing education as were applied years ago by the medical profession in its effort to improve educational standards in medical schools.

Nursing schools of a high standard must receive sufficient financial support to maintain full time instructors and to allow students sufficient periods for class work and hours for study. Maids are provided in many hospitals to perform numerous household duties, in the past performed by students. This also requires the employment of more graduate nurses which has increased the cost enormously and one may confidently expect that the cost of hospital nursing service will increase rather than decrease. An active interest on the part of nursing educators seems to point to a new plan of nursing education, the laboratory work and the teaching of basic sciences carried on as a part of the public school system in junior colleges or universities, requiring of the hospital only the bedside teaching. This would permit student nurses to provide a service comparable to that supplied by graduates and at

the same time would place the responsibility of the basic scientific education on the school system, thus relieving hospitals maintaining good schools of this financial burden.

The charge for graduate nursing service is not excessive. The acceptable graduate must be well prepared and have devoted years in preparation, after a reasonable basic education. She works under very trying conditions and on the average she is employed but about twenty-two days per month, and, during the entire time she must maintain a home as do other employed persons. Her income is about fifteen hundred dollars or less annually, hardly comparable under normal conditions to many employed with much less preparation. Her services are indispensable, her active years are short, and were it not for the satisfaction that comes from giving an altruistic service she would not seek to remain in this field.

Special nurses are often employed unnecessarily and their services constitute a severe financial drain and increase the per capita cost in a manner that might be avoided if they were employed only because of the professional requirement of the patient. The National Committee on Nursing Education in a survey made on the need of supplying special nurses, studied 1892 cases in which special nurses had been employed. This report states that the doctor in charge of the case urged a special nurse in but forty per cent of these cases, in thirty-three per cent a special nurse was ordered because the family desired a better service than that supplied by the hospital, in twenty-two per cent the patient demanded the special nurse because she felt that

the nursing service was inadequate; the hospital suggested a special nurse in but three per cent of the cases and in two per cent a special nurse was provided for no reason except that friends of the patient who had enjoyed hospital care had been so provided.

A perfectly legitimate subject for discussion is just what constitutes adequate nursing care. The hospital must provide a service to cover reasonable demands, but that service which requires an additional burden for the hospital to carry, without materially meeting the real professional needs of the patient, should not add to the burden of per capita cost. The patient's feelings must enter into any consideration of the subject. An agreement between the physician, the hospital and the patient, or her family, will at frequent intervals partially or entirely eliminate the demand for special nurses, when she is employed only to satisfy the unreasonable whims of someone. The charges for her services, when demanded for no good professional reason mount with increasing criticism as a charge against the hospital when the institution is an innocent victim of a situation which develops without profit to it and with no need on the part of the patient. A necessary nursing service should be demanded, but patients require protection in this hour of need against the necessity for paying for a special nurse when such care is not required.

The advancement of medical science through research is generally accepted as a proper function of a modern hospital. The goal of such activity requires that we increase our effective knowledge in the interest of the pa-

tient and his prompt recovery. Due to advancements made through clinical research, miracles in the treatment of disease come daily within the experience of all of us. When properly conducted and supervised, research promotes understanding of the underlying mechanism of disease and furnishes a better background for diagnosis and treatment. Clinical research stimulates better work on the part of the staff as it engenders an inquiring frame of mind. Generally it is recognized that effective clinical research can be carried out only in the hospital.

The proper use of material already provided will supply a satisfactory basis for clinical studies not now used to full advantage. As most of the elements required in any research problem are usually supplied by the hospital itself, it would follow that a greater use might be made of the facilities found available in any well organized institution. Well kept records include a thorough history, the results of physical examination, and the usual laboratory studies on all patients admitted. Such records, while of value during the time the patient is under immediate care, become of increasingly greater value when they are effectively used as a basis for study and to draw conclusions from a series of cases treated. Records should be made easily accessible to any member of the staff who desires to make a study of a series of cases and the record room may prove to be the incentive for conducting numerous further studies. A variety of clinical problems yet to be solved may be approached with no expense involved when effective use is made of the material already at hand. Such a

program would have the aggressive support of any hospital administration because of the actual accomplishment in better diagnosis and treatment, and the stimulation towards the completion of better and more complete records. Any program mutually arranged would provide for the beginnings of clinical study, complete records easily accessible have effective use.

Scientific enthusiasm is always a laudable quality in any member of the staff but it is not conducive to economy. Dr. Follansbee believes that, "the interesting case is an invitation to use all known tests applicable to it as a check against the reported findings of others. The repetition of such tests during the hospital stay of the patient and the agreement of such tests with expected results are sources of intense satisfaction to the physician who has ordered such tests. The justification however for making repeated tests of no particular importance except to satisfy the clinician is in raising the standards of medical inquiry and tending to stimulate additional studies which apply to patients suffering with similar disease, but repeated tests of such character can hardly be justified on any other ground." A comparison of numerous "interesting cases" where expensive laboratory investigations and other procedures have been carried out might point the way for standardized procedures, modified only as the problem changes, and provide an end result which justifies such an expensive program.

Without any desire to give offense, I desire to refer to certain extravagances of visiting physicians which add to the per capita cost. Care here might result

in a savings covering numerous minor items which accumulate over a period of years and tend to increase the cost of care to the patient or to the hospital. There are savings that may be made in the professional care without harm to the patient. They may not be large nor impressive, but to the patients who have difficulty in making payment for the expensive necessary service, they will be appreciated and where payment is not made by the patient, the cost to the hospital is material. According to Dr. Follansbee, "there are times when all the diagnostic facilities of the hospital and the acumen of the staff are insufficient to make a diagnosis but there are other times when the diagnosis is so evident that expensive diagnostic procedures can merely be confirmative of what is already known. It is therefore an extravagant and unnecessary cost. A patient suffering from typical gallstone colic with a history of repeated attacks but otherwise normal on physical examination, needs no intravenous dye or X-ray examination to make the proper diagnosis." Internes require that hospital facilities shall be available in order that they may be taught all that a hospital can teach. It is questionable whether they would not learn more and be more self-reliant if the scientific laboratory were displaced in cases such as the one mentioned, by the more consuming teaching of the art of history taking and physical examining and the conclusions to be reached thereby.

With the lure of modern advertising in the field of new preparations, physicians are confronted with a multitude of patented, copyrighted and proprietary remedies. The art of pre-scrib-

the nursing service was inadequate, the hospital suggested a special nurse in but three per cent of the cases and in two per cent a special nurse was provided for no reason except that friends of the patient who had enjoyed hospital care had been so provided

With the lure of modern advertising in the field of new preparations, physicians are confronted with a multitude of patented, copyrighted and proprietary remedies. The art of prescribing

ing has almost gone out of fashion with the advent of detail men and their willingness to serve in providing stock preparations sold under attractive titles. Such remedies when they appear on the market are several times more expensive and no more effective than remedies available in the United States Pharmacopeia. Recently a comparison was made in a very well organized hospital to determine the comparative cost of drugs and standard preparations listed, with similar proprietary preparations used because of the demand made by the staff and others concerned. It was found that a cost approximately four times greater on the average was carried by the hospital for proprietary remedies supplied as against the standard preparations that might replace them. In another hospital with a three thousand dollar stock of standard preparations with no proprietaries listed, the cost of drugs per patient with an acute condition totals sixty-seven cents. Twenty-two cents of this was paid for biologics and but forty-five cents covered the necessary required medications. Attention to the remedies prescribed, the standards used and the copyrighted names found on the shelves in any hospital pharmacy, will be of sufficient interest to the hospital and the physician to justify a further study.

Routine prescribing of costly hypnotics and sedatives night after night simply to satisfy a patient's whim is expensive and vicious. Barbitol and similar hypnotics are not habit forming drugs, but there is such a thing as a habit of not sleeping without the drug which develops in certain classes of patients. Morphine sulphate is giv-

en much too frequently in many hospitals, particularly those of the public type. It is quite possible without any injury to the patient to reduce the use of the morphine and its derivatives very materially with beneficial results to the patients and a decreasing cost for unnecessary expenditures. In one hospital with a very large emergency and surgical service handling patients with acute illnesses the total morphine use averages but six and one-half grains per day. There is a deplorable waste of dressings, particularly in the accident service of any hospital. The house staff may be taught economy in the use of gauze, bandages, dressings, adhesive and in the use of drugs for routine prescribing. One-half the amount of bandage ordinarily used, if properly applied, will hold the dressing in place better than twice the amount improperly applied. The hospital should supply abdominal pads of sufficient size only and dressings should be adopted for use to the type of case at hand. These are matters of economical practice that demand our mutual interest. Team work between the hospital administration and the staff is dependent upon the personality of one leader—enthusiasm, patience, fairness, generosity and tact can develop team work and do wonders in any institution. Such a leader in a hospital is usually the superintendent and he may be either a layman or a professional man. If he presents the right qualifications he will attract the various divisions engaged in hospital work and establish a well-functioning machine. The small extravagances which have been mentioned, as well as many others, which enter into increased per capita cost can

be decreased and often times entirely eliminated if the superintendent will apply his qualities of leadership and the visiting staff will pride themselves on their ability to effectively treat the patient, demanding only the necessary service and requiring for the patient no extravagances which may be eliminated

There are many other problems which demand our attention but which may be only mentioned as a basis for mutual interest between the physician and the hospital. Hospitals are unjustly criticized because of the increasing costs and many times with no responsibility whatsoever. The entire cost of medical care including professional services rendered by the physician, the care of the patient in the hospital and the ability of people of moderate means to pay for such services continue to challenge the best efforts of trained investigators in this field. As physicians interested in hospitals, we are confronted with the demand to supply to every person the necessary medical care at a cost within the power of the ordinary citizen to pay. Judge Rosen of New Orleans has said that, "This great and rich nation is not likely to rest content until its citizens the country over receive the best possible care. To meet the tremendous problems of distributing medical service to a hundred million people, it is clearly evident that charitable gifts will not suffice. Either the state will have to take the responsibility, or representatives of the general public must

unite to find the best methods whereby people will get good medical care at a fair price."

Medical practice both in the hospital and at home is definitely passing through a crisis from which it may be assumed that marked changes will require a readaptation to the times. From an editorial appearing in the March, 1932, *ANNALS OF INTERNAL MEDICINE*, I would conclude by quoting "It is a time for those who, by reason of official position or by reason of unusual ability, are the leaders of our profession to put their minds together and help us to chart our course. It is not the time for reactionary impulsive action, impractical experiments, or challenging attitudes. We must be on guard against impractical panaceas which come either from within or from without the profession, and hope that no such panaceas will obtain legislative approval.

"It is not unlikely that there is to be a distinct change in the character and type of medical practice in the next generation. A variety of social movements affecting medicine are under way, and their development is not to be stopped. State medicine is edging its way in and is not to be entirely kept out. That concessions must be made, compromises accepted must be recognized by the rank and file of the profession. It will be the obligation of our leaders to guide, so far as they may, these movements, and to advise us when such concessions are necessary and compromises essential."

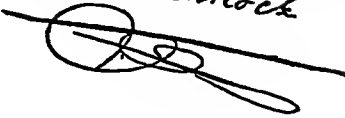

Anton van Leeuwenhoek

FIG 1

Antony van Leeuwenhoek

1632-1723

By CARL V WELLER, M S , M D , F A C P , *Ann Arbor, Michigan*

ANTONY van Leeuwenhoek was born in the old Dutch city of Delft, on October 24th, 1632. For a number of years both before and after that memorable date, events of prime importance were occurring in the awakening scientific world. In that year William Harvey was fifty-four years old, and four years before that date Harvey had written in the dedication of his *Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus*, addressing the President and members of the Royal College of Physicians "I have already and repeatedly presented you my learned friends, with my new views of the motion and function of the heart, in my anatomical lectures, but having now for more than nine years confirmed these views by multiplied demonstrations in your presence, illustrated them by arguments, and freed them from the objections of the most learned and skillful anatomists, I at length yield to the requests, I might say entreaties, of many, and here present them for general consideration in this treatise

"* * * * * And as this book alone declares the blood to course and evolve by a new route, very different from the

ancient and beaten pathway trodden for so many ages, and illustrated by such a host of learned and distinguished men, I was greatly afraid lest I might be charged with presumption did I lay my work before the public at home, or send it beyond seas for impression, unless I had first proposed the subject to you, had confirmed its conclusions by ocular demonstrations in your presence, had replied to your doubts and objections, and secured the assent and support of our distinguished President." And thus, in 1628, was the truth in regard to the motion of the blood, a circular motion, made known.

While Leeuwenhoek was yet a boy in his early teens, an interesting research club was in process of birth in Oxford. Wearied of arguments on religion, on state affairs and on the then current economic depression, a group of young men (their average age was but thirty-four) were holding weekly meetings, "sometimes at Dr Goddard's lodgings, sometimes at the Mitre in Wood Street hard by," or at Dr Petty's lodgings "because of the conveniences we had there (being the house of an apothecary) to view, and make use of, drugs and other like matters as there was occasion." A common interest in Natural Philosophy

ANTONY van Leeuwenhoek was born in the old Dutch city of Delft, on October 24th, 1632. For a number of years both before and after that memorable date, events of prime importance were occurring in the awakening scientific world. In that year William Harvey was fifty-four years old, and four years before that date Harvey had written in the dedication of his *Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus*, addressing the President and members of the Royal College of Physicians: "I have already and repeatedly presented you my learned friends, with my new views of the motion and function of the heart, in my anatomical lectures, but having now for more than nine years confirmed these views by multiplied demonstrations in your presence, illustrated them by arguments, and freed them from the objections of the most learned and skillful anatomists, I at length yield to the requests, I might say entreaties, of many, and here present them for general consideration in this treatise."

"* * * * * And as this book alone declares the blood to course and evolve by a new route, very different from the

ancient and beaten pathway trodden for so many ages, and illustrated by such a host of learned and distinguished men, I was greatly afraid lest I might be charged with presumption did I lay my work before the public at home, or send it beyond seas for impression, unless I had first proposed the subject to you, had confirmed its conclusions by ocular demonstrations in your presence, had replied to your doubts and objections, and secured the assent and support of our distinguished President." And thus, in 1628, was the truth in regard to the motion of the blood, a circular motion, made known.

While Leeuwenhoek was yet a boy in his early teens, an interesting research club was in process of birth in Oxford. Wearied of arguments on religion, on state affairs and on the then current economic depression, a group of young men (their average age was but thirty-four) were holding weekly meetings, "sometimes at Dr Goddard's lodgings, sometimes at the Mitre in Wood Street hard by," or at Dr Petty's lodgings "because of the conveniences we had there (being the house of an apothecary) to view, and make use of, drugs and other like matters as there was occasion." A common interest in Natural Philosophy

and a conviction that the truth was to be found by going to Nature and not in man-made canons bound this group together. John Wallis, later a mathematician of note, wrote that they confined themselves "to philosophical inquiries, and such as related thereunto; as Physick, Anatomy, Geometry, Astronomy, Navigation, Staticks, Mechanicks, and Natural Experiments." Those interested in medical matters must have influenced decidedly the complexion of the entire group. With Robert Boyle, Robert Hooke, Seth Ward and Matthew Wren, there were to be found among the medical group, the young anatomist, Christopher Wren, Thomas Willis, who was already interested in the brain and nervous system, Jonathan Goddard, whose name became coupled with his remedy, Goddard's drops, Francis Glisson, after whom the capsule of the liver is named, George Ent, intimate friend and executor of Harvey, Charles Scarbrough, who was to attend Charles II in his last illness, William Petty, who was Cromwell's First Physician to the Army in Ireland, and Christopher Merritt, who became the first custodian of the medical library which Harvey gave to the College of Physicians.

About 1658, the meetings of this research club ceased to be held in Oxford, for a number of its members had then moved to London, and, in 1662, Charles II bestowed upon the organization a royal charter. Such was the conception and nativity of The Royal Society of London.

Samuel Pepys, the diarist, happened to be present at Whitehall on January 9, 1665, when The Royal Society received this charter, the King signing

as 'Founder' and James, the Duke of York, as 'Fellow'. Pepys wrote as a part of his entry for that date "Up and walked to Whitehall, it still being a brave frost, and I in perfect good health, blessed be God! In my way saw a woman that broke her thigh, in her heels slipping up with the frosty street To the Duke, and there did our usual work. Here I saw The Royal Society bring their new book, wherein is nobly writ their charter and laws, and comes to be signed by the Duke of York as a Fellow, and all the Fellows' hands are to be entered there, and he as a monument; and the King hath put his with the word Founder."

The Curator of Experiments to The Royal Society during this period was Robert Hooke. Interested in all things mechanical, he was the inventive genius of his age. He, himself, estimated his inventions at not fewer than a thousand. He was particularly interested in microscopy, and in 1665, only three years after The Royal Society had received its charter, Hooke published his *Micrographia or Some Physiological Descriptions of Minute Bodies Made by Magnifying Glasses With Observations and Inquiries Thereupon*. In this book he applied the name "cells" to the structure of cork. This marks the beginning of knowledge of the cellular structure of living things. Hooke used a condensing system for increasing the light upon the object under investigation, and, according to his own account, his microscope had two or three lenses. Yet he recognized the fact that the simpler the optical system the better the illumination and definition, for he wrote "But whenever I had occasion to ex-

amine the small parts of a Body more accurately, I took out the middle Glass, and only made use of one Eye Glass with the Object Glass, for always the fewer the refractions are, the more bright and clear the Object appears. And therefore, 'tis not to be doubted, but could we make a Microscope to have only one refraction, it would, *ceteris paribus*, far excel any other that had a greater number." At that very time just such microscopes as Hooke coveted were being made in Delft by the young Dutchman, then 33 years old, whose tercentenary we celebrate! To him we must now turn our attention.

Descended from a long line of Delft brewers, upon the death of his father, Philip Antony van Leeuwenhoek, the young Antony was sent away to school at Warmond, and later to Benthuisen where he was under the care of an uncle who then held some official position. Presumably it was planned to have him follow his uncle's career as an officeholder, but at the age of sixteen years he was put into a clothier's establishment in Amsterdam where he made use of his special aptitude in elementary mathematics as bookkeeper and cashier. His work in the draper's shop could not have continued for more than five or six years, for, at the age of twenty-two, he had returned to Delft and was married. Six years later he secured appointment to the position of "Chamberlain of the Sheriff" of Delft. His commission is still in existence and in it his duties are clearly set forth. Wynter-Blyth translated them as follows: "To open and shut the door of the chamber, both on ordinary and extraordinary days of

meeting; to show honor and respect to the councillors, to keep inviolate anything he might hear in the council chamber, to keep the chamber clean, to make the fires, also to preserve the place from fire, and to do all that a good and faithful chamberlain should do." In short, Antony van Leeuwenhoek was made janitor of the town hall. This appointment gave him a small, but certain, income. He held this position for thirty-nine years and the salary was paid him until his death. As Wynter-Blyth puts it, just "as the Scots made their greatest poet an exciseman, so the Dutch made their philosopher a beadle."

For Leeuwenhoek, and for the broadening stream of scientific knowledge, this official appointment was of the greatest advantage. It permitted him to earn his living in about as simple and non-time-consuming a manner as could well be imagined. We must believe that he attended to those simple duties honestly and well, but they could not have engaged more than a small fraction of his time. At just what period he commenced to construct microscopes and to make observations with them is not known, but it was certainly a number of years before 1673 when, at the age of 41 years, he was first introduced to The Royal Society of London by Reinier de Graaf. This first communication can be found on page 6037, Volume VIII, of the *Philosophical Transactions* and it bears the title "A specimen of some observations made by a Microscope contrived by Mr Leeuwenhoek, concerning Mould upon the skin, flesh, etc., the Sting of a Bee, etc." From that time on, as will appear, the Dutch

microscopist became a frequent contributor

For Leeuwenhoek, a new exploration in the realm of the sub-visual meant first the construction of a new microscope, for so inconvenient and limited were the means provided for bringing the object to be observed into proper relationship to the lens that to a certain extent each instrument was constructed to serve a special purpose. These microscopes, which might better be called magnifying glasses, Leeuwenhoek built entirely with his own hands

not simply a polished spherical globule of glass such as others had used, securely held between two plates. These were joined by several small rivets or screws, placed near the margin. The plates were of silver, gold or brass, and were pierced by a small opening, corresponding to the position of the lens. Attached to these plates there was a small object table borne upon a movable screw and carrying also a smaller adjustable object holder to retain and move the object under examination (Figure 2.)

FIG. 2 Front and back views of a Leeuwenhoek microscope. The double convex lens is in position at *d*. At the points marked *e* are six screws or rivets for holding the two metal plates together. The handle, *a*, carries also a threaded screw, *g*, for varying the height of the object carrier, *k*. This, in turn, bears the object holder, *i*, with arrangements for altering the position of the object.

For some of them he even extracted the silver from the ore himself. The lenses he likewise formed and polished, and therein lay his special skill.

From his own descriptions, and from drawings prepared by others, it is known that practically all of the microscopes made by Leeuwenhoek consisted of a very small double convex lens,

Our knowledge of the microscopes made by Leeuwenhoek comes largely from two sources. He bequeathed twenty-six of them to The Royal Society, and these, although no longer known to exist, were described and illustrated by Baker in his book *Employment for the Microscope*, London, 1753. At a visual distance of eight

inches from the lens, these gave magnifications ranging from 40 to 160 times. However, a Leeuwenhoek microscope in Utrecht was found to magnify 270 fold.

Harting described the auction catalogue of Leeuwenhoek's microscopes as they were put up for sale on May 29, 1747. In this catalogue it is set forth that Leeuwenhoek left no less than 247 complete microscopes, many with an object to be viewed still in position, also 172 additional lenses mounted between plates, a total of 419 lenses. Three of these lenses were of rock crystal (Amersfoorte Diamanten). Two microscopes were said to have two lenses and one three, from which it has been assumed that Leeuwenhoek made use of doublet and triplet lenses. It is probable, however, that these were instruments with two and three simple lenses mounted at as many separate openings. Of the group included in this sale, 160 had silver plates for mounting the lens, and three had plates of gold. The remainder were of brass. The catalogue gave the names of the purchasers, who were all Dutch. Yet, in 1858, Harting commented upon the extreme scarcity of van Leeuwenhoek microscopes in Holland. (This should furnish the basis for an intriguing quest for the collector.)

Although Hooke made use of a condensing system in order to increase the illumination of the object, there is no evidence that Leeuwenhoek employed such a device. His microscopes were made to be held in the hand, directed toward the source of light. In 1689, however, he described for The Royal Society a perforated mirror with a lens

at the orifice which would increase the amount of light incident upon the object which was being viewed.

With such instruments as these, Leeuwenhoek examined, described and drew those natural objects which attracted his interest and for which he could devise the means of inspection through his magnifiers. Sometimes special apparatus had to be contrived for holding immobile, and yet alive, such material as tadpoles and eels. For observation of the circulation he used a special stand provided with perforated plates for the insertion of glass tubes to contain the living subject. The auction catalogue to which reference has already been made listed eight such special stands of silver and four of brass. An illustrator of some fifty years ago has supplied the tube and its imprisoned occupant, and this apparatus has been reconstructed in facsimile.

The objects chosen by this adventurer in the unknown were of the most diverse nature. The sequence of his investigations seems to indicate a lack of any systematic pursuit. Yet we must bear in mind that Leeuwenhoek was driven by dynamic curiosity, for he was viewing that which never before had been seen by the human eye. It mattered not whether the object of his inspection might be inanimate or animate, animal or vegetable, native or the gift of some merchant returning from a distant land, if it did but offer an as yet unknown morphology awaiting description. For human authority he cared not at all. The views of his predecessors seldom concerned him, but he sought truth in Nature, and if others denied the accuracy of his observa-

tions, Nature was again the court to which to appeal.

Thus we find among the subjects investigated by Leeuwenhoek an extraordinary variety. The lists compiled by Richardson are sufficiently complete to indicate the range, and I follow his grouping in part.

Animals of different kinds. Animalcules in water of various sorts and in infusions, the ant, cantharides; cochineal, various fish, the flea, the fly, the frog; the liver fluke of sheep; the gnat, locust; louse, maggots, millipeds, mites; sea and fresh-water muscels, the scorpion, shrimp; silkworm; snails; spiders; tadpoles; the viper, and its poison; the weevil, or corn beetle; and the whale.

Special structures and functions of animals. Acids in the stomach, and their part in digestion, the blood, its globules, its minute circulation, its coagulation, and the frequency of its course from the heart; the structure of bones, the brain of various animals; the eye and its crystalline lens; the visual organs in the eyes of the silkworm moth, of a beetle and of a shrimp, the optic nerves of the fly; feathers of birds and the scales of insects, muscle fibers; the generation of animals, with refutation of spontaneous generation, the spermatozoa of many species; hair; the structure of the heart in various species, the intestines, their membranes and vessels, the structure of nerves; epithelial cells of the lining membrane of the mouth; the structure of the spleen; and the coating upon the tongue in fevers.

The structure of plants and of vegetable products: The ash tree; the beech, ebony, wood, elm timber; fir

timber, willow, boxwood; the barks of various trees; the cocoa tree and nut, coffee; corn stored in granaries, cotton; the structure and production of oak galls; excrescences on thistles and on willow leaves, the hop, the lime tree; various spices, including mace, pepper, nutmeg, and sage; the nettle; the root of pareira brava; Peruvian bark, peat, the periwinkle; rushes and their formation, the seeds of various trees and plants, including tobacco; the nature and properties of tea, vinegar, and wheat.

It is evident that there are but few fields of modern microscopical investigation in which the researcher need not have knowledge of the work of Leeuwenhoek if he would know the firstlings of his subject. Yet Leeuwenhoek was an uneducated man. Aside from his knowledge of elementary mathematics his experiences at school had little or no influence upon his work. He spoke, read and wrote Dutch, but he knew no other language. Neither did he travel. There is no indication that he ever addressed a scientific society or in any manner set forth his discoveries in public address. Yet as his fame grew, he was visited by his contemporaries in scientific investigation and by various royal personages, including Peter the Great of Russia and Queen Mary of England. To Queen Mary he gave a pair of his microscopes of the same sort as those which he later devised to The Royal Society, of which, in 1680, he had been elected a Fellow (not a Corresponding Member as is sometimes stated). He never attended a meeting of The Royal Society and yet became its most prolific contributor. To it his discov-

eries were imparted by letters, perhaps as many as three hundred and seventy-five communications in all, including the various lesser explanatory notes and answers to queries. The French Academy of Sciences, of which he was elected a Corresponding Member in 1697, received twenty-six letters, and still others were written to individuals. While Leeuwenhoek was yet living, collections of his letters appeared from time to time but there were some which were not included in such compilations. In 1798-1801, Samuel Hoole published a two volume collection of the letters of Leeuwenhoek, consisting of selections concerning over one hundred and fifty topics. All reference to the male reproductive cells and to the generation of animals, comprising the most numerous and probably the most valuable group of papers was omitted, apparently on the ground of indelicacy.

The temptation to quote extensively from the letters of Leeuwenhoek is indeed great, but only a few selections can be made. Unfortunately, some of the simple homely quality of the original Dutch is lost in the translations.

COCHINEAL

Leeuwenhoek had communicated to The Royal Society in 1691, an account of the mode of preparation of cochineal grains, as he had had it from an old Spaniard who had lived many years in the West Indies. In 1704, he examined this dye stuff microscopically, and reported his findings in a long letter from which the following are excerpts.

"A merchant of Amsterdam writes, that it is impossible, and altogether incredible that the drug called cochineal should be,

as I have asserted, flies, or any sort of animal endued with wings, head or feet, not only if we consider the vast number of them that are brought in every fleet from America, for you will find that two of the largest of these particles, eight of the middling sort, and twenty of the smallest, scarcely weigh a gold grain, so that in a pound of them, at a medium of large and small, one may count 102,400 particles, now in a fleet that brings 200,000 pounds of this drug, what a vast number of animals there must be? Besides, says he, where can you find men enough, who at the proper time of the year shall catch these insects, and dismember every individual by pulling off its head, legs and wings, etc., so that he concludes that cochineal must needs be a fruit, or the excrescence of some kind of plant.

"Though I am convinced that cochineal is nothing else but the trunk or hinder part of a living creature, and was persuaded also that the cochineal animals, like other insects from worms, are changed into flies, yet for further satisfaction, I have renewed my inquiries upon this subject, and in so doing I find reason to reject some of my former positions, being now fully convinced that the cochineal animals are not produced from worms, but at once bring forth their own likeness

* * * * *

"Now for further satisfaction, I took several particles of this same cochineal, [figure 3] both of the largest and smallest, and having dissected them, I found that they had all eggs in their bellies, excepting only one that was exceeding small. Having opened some of the largest trunks, and separated the eggs, which I took out of their bodies, and counted them, I judged that there were above 200, and having observed several of them with my microscope, I could perceive not only a membrane or shell on most of them, but also an animalculum of an oval shape included in the said shell, and almost as large as the shell that contained it, which seemed at first very surprising, and almost incredible in so small a species of fly as the cochineal, till by a very nice and long inquiry I was fully satisfied, that it was really an animalculum that lay within it. I pursued this operation with so good success,

that I not only separated the egg-shell from the animalculum but in some of them I could perceive their legs also orderly folded up against their body, and could separate them from it, especially in such as were full grown, nay, in some I even discovered the several joints of the legs, and thus in the space of two days I saw the legs of 100 animalcula, many of which in my handling were broken off, and lay by themselves"

DESCRIPTION OF A LOUSE FEEDING 1674

"Having formerly spoken of the louse, her sting, etc, I cannot here omit to say something of what I have seen within that creature I have several times put a hungry louse upon my hand, to observe her drawing blood from thence, and the subsequent motion of her body which was thus The louse having fixed her sting in the skin, and now drawing blood, the blood passes to the fore part of the head in a fine stream, and then it falls into a larger round place, which I take to be filled with air This large room being, as to its fore part, filled about half full with blood, then propels its blood backward, and the air forward again, and this is continued with great quickness, while the louse is drawing the blood, except that at times she stops a little, as if she were

tired and recollects herself, a motion like that, it seems, which is in the mouth of a sucking infant from thence the blood passes in a fine stream into the midst of her head, that being also a large round place, where it has the same motion Hence it passes in a subtile stream to the breast, and thence into a gut, which goes to the hindmost part of the body, and with a curvity bends a little upwards again In the breast and gut the blood is, without intermission, moved with great force, and especially in the gut; and that with such strong beatings downward, and with such a retrocourse and contraction of the gut, that a curious eye cannot but admire that motion In the upper part of the crooked ascending gut, which is very straight [i.e., narrow], now and then a little blood crowds through, which returns not back, and here I presume is a little valve the blood, that is thrust through here, stands still, and soon receives another nature, becoming of a watery colour, and in this watery liquor there appear some blackish sandy particles, having a confused motion, which grow in size and being grown as large as sand is to our eye, the said particles join themselves close and firm together, as it were in one mass, and then shoot down to the anus, carrying with them, in case the louse have much

FIG. 3 Drawings by Leeuwenhoek to illustrate the anatomy of the cochineal insect Figures 7 to 15 deal with this subject, all except the first showing stages of the embryos which lie in the body of the adult female

blood in her body, a little aqueous blood These excreted particles appear like the excrement of a silk-worm"

THE FIRST PROTOZOOLOGY AND THE FIRST BACTERIOLOGY

Dobell wrote of Leeuwenhoek as the first of the protozoologists and expressed himself as fully satisfied that no successful effort had ever been made to refute that contention In the minute living things which he discovered in so many homely sources, Leeuwenhoek evidently took great delight He designated them by terms which can be translated 'little animals', 'beasties', or 'little creatures', as if he had a tender feeling towards them Perhaps he felt the fundamental biological unity of all living things At any rate, he reasoned that even the smallest of them must have an internal morphological organization like that of the larger animals Thus he was led to speculate, with detailed mathematical calculations, upon such hypothetical possibilities as the probable size of the blood capillaries in minute unicellular organisms

I select for quotation here Leeuwenhoek's description of one of the minute forms of life which, in 1675, he saw "in rain water, which had stood but a few days in a new earthen pot, glazed blue within" This is the first description of *Vorticella* An abridged version of this letter appears in the Philosophical Transactions of The Royal Society for 1677, but I use Dobell's translation which not only is more complete but also strives to catch the flavor of the original Dutch

"Of the first sort of creatures that I discovered in this water, I saw, after divers observations, that the bodies consisted of

5, 6, 7, or 8 very clear globules, but without being able to discern any membrane or skin that held these globules together, or in which they were inclosed When these little animals moved themselves, they sometimes stuck out two little horns [optical section of the wreath of cilia round the peristome], which were continually moved, after the fashion of a horse's ears The part between these little horns was flat, their body else being roundish, save only that it ran somewhat to a point at the hinder end, at which end it had a tail, near four times as long as the whole body, and looking as thick, when viewed through my microscope, as a spider's web At the end of this tail there was a pellet, of the bigness of one of the globules of the body, and this tail I could not perceive to be used by them for their movements in very clear water These little animals were the most wretched creatures that I have ever seen, for when, with the pellet, they did but encounter any particles or little filaments (of which there are many in water, especially if it hath but stood some days), they stuck entangled in them, and then stretched their body into an oval, and did struggle, by strongly extending themselves, to get their tail loose, whereby their whole body then sprang back toward the pellet of the tail, and their tails then coiled up serpent-wise, after the fashion of a copper or iron wire that, having been wound close about a round stick, and then taken off, retains all its windings This motion of extension and contraction of the tail continued, and I have seen several hundred of these little animals, caught fast by one another in a few filaments, lying within the compass of a coarse grain of sand"

In the same letter Leeuwenhoek wrote of other sorts of living creatures which were so small that he was not able to give them a definite figure The larger forms he demonstrated to spectators, but of the smallest he wrote that they were not seen by others for he saw them by another microscope which he reserved for himself alone. These smallest forms were probably bacteria

Then, in 1684, he wrote to The Royal Society as follows

"Though my teeth are kept usually very clean, yet when I view them in a magnifying mirror, I find growing between them a little white matter, as thick as wetted flour in this substance, though I could not perceive any motion, I judged there might probably be living creatures I therefore took some of this flour, and mixed it either with pure rain water wherein were no animals, or else with some of my spittle, having no animals nor air bubbles to cause a motion in it, and then to my great surprize perceived that the aforesaid matter contained very many small living animals, which moved themselves very strangely. The largest sort were not numerous, but their motion strong and nimble, darting themselves through the water or spittle, as a jack or pike does through the water The second sort spun about like a top, and were more in number than the first In the third sort I could not well distinguish the figure, for sometimes it seemed to be an oval, and other times a circle these were exceedingly small, and so swift, that I can compare them to nothing better than a swarm of flies or gnats, flying and turning among each other in a small space * * * * The number of these animals in the scurf of a man's teeth are so many, that I believe they exceed the number of men in a kingdom For on the examination of a small parcel of it, no thicker than a horse-hair, I found so many living animals in it, that I guess there might have been 1,000 in a quantity of matter no larger than the one-hundred part of a sand [grain]"

Of the many ingenious controls which Leeuwenhoek devised, bearing upon the question of origin and survival of protozoa and bacteria, no description can be given. With his infusions of pepper, ginger, and nutmegs; his search of waters from various sources and after various periods of storage; his comparisons of the living creatures in the deposits between the much washed teeth of ladies of his

acquaintance and from the neglected teeth of old toppers; his personal experiences with mouth washings with strong vinegar and hot coffee, he learned much of the life and possibility of survival of these minute forms. Thus he is justly placed by de Kruif as "the first of the *Microbe Hunters*"

SPERMATOOA

Many of the letters of Leeuwenhoek dealt with the male reproductive cells, which he observed in numerous species His first letter on this subject was dated November, 1677, and was published in the Philosophical Transactions for 1679. In this he makes it clear that he first saw spermatozoa at the suggestion of Johan Ham who had discovered them while a student at Arnheim Ham never published his observations Priority of description then rests with Leeuwenhoek At this time, also, he described for the first time the crystals of spermine phosphate Urged by the Secretary of The Royal Society to extend his observations, he sent on March 18, 1678, drawings of the animalcules which he observed in the seminal fluids of the dog and rabbit, and by 1683 Leeuwenhoek had examined the seminal animalcules in almost all classes of animals and had substituted the theory of generation *ex animalculo* for that of *ex ovo* Some believed that he had discovered the homunculus of Paracelsus but in a letter published in 1699 he stated emphatically that he had never seen the semblance of the human form in the structure of the spermatozoon Statements of various biographers to the contrary are due to a curious error Leeuwenhoek had accepted seriously a

certain communication which was falsely signed Dalenpatius, and repeated the imaginary cuts of the practical joker, who was its author, in commenting adversely upon it. These crude figures showed the spermatic homunculus in the act of bursting forth from its investing membrane. Due, in part, to an error in placing these figures, it was assumed that they represented Leeuwenhoek's opinion, whereas the contrary was the case. He did believe, however, that he had distinguished sexual differences between spermatozoa, and suggested that they might be able to reproduce themselves as do other minute animals, but if so, the small stage must be passed through very rapidly for they were found to be all of approximately the same size.

THE CIRCULATION OF THE BLOOD

Harvey had described and proved the existence of a circulation, Malpighi had discovered the capillaries, but Leeuwenhoek was the first to see the

FIG 4 The capillary loops as seen by Leeuwenhoek

FIG 5 Above are blood corpuscles of various species, and in fig 7, the passage of the corpuscles from artery to vein through the capillaries

passage of the corpuscles of the blood from the arterial to the venous channels. His first success was with the tadpole. I quote from Hoole's translation of the letter in which Leeuwenhoek described this observation:

"Upon examining the tail of this creature, a sight presented itself, more delightful than any that my eyes had ever beheld, for here I discovered more than fifty circulations of the blood [figure 4], in different places, while the animal lay quiet in the water, and I could bring it before the microscope to my wish. For I saw, not only that the blood in many places was conveyed through exceedingly minute vessels, from the middle of the tail towards the edges but that each of these vessels had a curve, or turning, and carried the blood back towards the middle of the tail, in order to be again conveyed to the heart. Hereby it plainly appeared to me, that the blood-vessels I now saw in this animal, and which bear the names of arteries and veins are, in fact, one and the same: that is to say, that they are properly termed arteries so long as they convey the blood to the farthest extremities of its vessels, and veins when they bring it back to the heart [figure 5]."

What manner of man was this whose interests covered so wide a range and who found something new wherever he searched? By his works, his many letters and certain extant portraits we must judge him. Unlearned in the scholastic sense, but by no means illiterate, an obstinately persistent searcher who never knew defeat; intellectually honest in that he described faithfully that which he *saw*, and carefully differentiated from it that which he *thought*, stubborn, selfish, for he reserved certain lenses and certain methods for himself alone; sensitive, but at the same time self-satisfied in

the knowledge of the superiority of his knowledge, Leeuwenhoek was above all else an overwhelmingly accurate man. When, in 1723, and at the age of ninety-one years, Leeuwenhoek was on his deathbed, he called to him his friend, Johannes Hoogvliet, and asked him to translate two more letters into Latin and send them to The Royal Society. They were received posthumously. Thus Antony van Leeuwenhoek was for more than fifty years a searcher for truth. He had a profound respect for Authority, but for him Authority was vested only in Nature.

Editorials

THE TERCENTENARY OF ANTONY VAN LEEUWENHOEK

On the twenty-fourth day of the month of this issue the scientific world celebrates the three hundredth anniversary of the birth of Antony van Leeuwenhoek. The phrase, "the scientific world," is used advisedly for there are few branches of science which do not owe much to the insatiable curiosity of this honest Dutchman. Particularly do the microscopists claim him for their own, the bacteriologists, protozoologists, and micro-phytologists, but the physiologists, chemists, and crystallographers likewise have a claim. A fuller appreciation than the editorial columns permit is published as the final article in this issue.

PRIMARY CARCINOMA OF THE LUNG IN THE MINERS OF JOACHIMSTAL

Editorial reference has been made in the ANNALS¹ to the accumulating evidence that radio-activity may be an important extrinsic factor in the etiology of cancer. Attention was called to the radio-activity of the ore in the oft-quoted Schneeberg mines, in which the miners have been known to suffer to a peculiar degree from pulmonary disease since this *Beigkrankheit* was described by Agricola in 1500. It is now well established that this illness

was very frequently primary carcinoma of the lung. Less has been known until recently in regard to the occurrence of a similar affection in Joachimstal, a mining town of about 8,000 inhabitants, situated on the Bohemian side of the Erz Mountains, in Czechoslovakia, about 30 kilometers southeast of Schneeberg. There is now available a delayed report of the investigations by Pirchan and Siki² in this village. Here the *a priori* assumption that a significant rôle is played by radio-active substances seems all the more justified for Joachimstal has been famous as a source of radium since the beginning of the present century. It was from pitchblende from this source that Mme. Curie isolated radium, and at the present time there is an annual production in the government factory of about two grams of radium chloride annually. The waters of the mines are strongly radio-active also. There had been knowledge of a considerable mortality from pulmonary disease among the miners of Joachimstal for a long time but proof of its cancerous nature was lacking. The first case of cancer of the lungs in a radium factory worker

¹EDITORIAL. Internal radiation in the causation of malignancy, ANN INT MED 1932 v, 932-934

²PIRCHAN, AUG, and SIKI, H. Cancer of the lung in the miners of Joachimstal (Joachimstal), Am Jr Cancer, 1932 vii 681-722

in this village was observed by Pirchan in 1926. During the period (1929-1930) covered by the investigation quoted, 19 miners died, of whom ten belonged to the active staff and nine were pensioners. Upon these it was possible to make postmortem examinations in but 13 cases. Nine proved to have cancer of the lungs.

As in the similar situation in the Schneeberg mines the etiological factor, the cancerogenic agent, has not been determined with certainty. These mines have in common the presence of arsenic compounds, some of which are volatile and are found in the air of the mines. Chemical analyses of human tissues have failed to show arsen-

ic, but this evidence is not conclusive. As to the content of radium emanation in the air of the three pits now being worked at Joachimstal, the conditions are very similar to those in the Schneeberg district. In various levels and at various times there is a great quantitative difference, ranging from 4 to 52 maché units, which corresponds closely with values up to 50 maché units as determined in the Schneeberg mines. Although yet unproved, radium emanation, exerting a cumulative effect when inspired for a period of years, must be considered the most probable extrinsic etiological factor in the primary carcinoma of the lungs in these miners.

Abstracts

The Chief Remarks to the First Graduating Class of the Medical Department of Duke University on the Occasion of the Planting of a Sprig of Ivy from 13, Notingham Gardens. By WILLIAM S. THAYER, M.D. (New England Jr. Med., 1932, cccvii, 563-570.)

Not to abstract—for it would be little less than sacrilege for the abstractor to mar the unity of this delightfully informal address—but to call attention to its very existence and place of publication is the purpose of this reference. All of that great host who hold Osler in loving memory through close association with him and the still greater host of those inspired by his life and works will read and reread this brilliant appreciation packed with reminiscences, by one who can say: 'For to us who were close to him during the last thirty years of his life, he will always stand out a figure apart from most other men.'

Cysts of the Dysentery-Producing Endamoeba Histolytica in a Baltimore Dog. By JUSTIN ANDREWS. (Am. Jr. Trop. Med., 1932, xii, 401-404.)

A wire-haired fox terrier, born and reared near Baltimore, became ill when about six months old and passed gelatinous, stringy, mucus-containing stools which were occasionally diarrhetic. In the simple smears from the stool, two types of amebic trophozoites were found, from the general appearance of which a tentative diagnosis of *Endamoeba histolytica* and *E. coli* was made. Subsequent examination of the stained smears showed in addition, both eight- and four-nucleated cysts, in all respects resembling the cysts of these two amebae respectively. The finding of cysts of *E. histolytica* in a naturally infected dog is apparently a unique observation. If the identification of the organism was correctly made, it means that this dog was a carrier and constituted

an available reservoir for pathogenic amebic infection in man and dogs

Lawrence-Moon-Biedl Syndrome By WILLIAM ANTHONY REILLY, A B, M D, and HANS LISSER, A B, M D, (Endocrinology, 1932, xvi, 338-357)

Two certain and two doubtful cases of the Lawrence-Moon-Biedl syndrome are reported, and are combined with 73 acceptable cases from the literature in a tabular analysis of this extremely interesting complex. The six cardinal symptoms—obesity, genital dystrophy, retinitis pigmentosa, mental deficiency, polydactylism, and familial occurrence—are by no means all invariably present. Such groupings as obesity, genital dystrophy, and retinitis pigmentosa, obesity, mental deficiency, and retinitis pigmentosa, and retinitis and polydactylism, are encountered. Unless the complete syndrome is present, familial occurrence is necessary for positive diagnosis. In the reported cases there are 25 with complete findings. Some authors have found symptomatic improvement on endocrine replacement therapy, using various combinations of thyroid with pituitary and ovarian extracts. The obesity and the mental retardation have been relieved to varying degrees by such management. Two of the cases reported in this paper have responded well to endocrine therapy. Loss of weight, increased animation, and definite improvement in vision have occurred.

Effect of Carbon Arc Irradiation on the Goiter-Producing Substance in Plants By BRUCE WEBSTER (Proc Soc Exp Biol and Med, 1932, xxix, 1070-1072)

Freshly harvested cabbage from a source which had previously been shown to produce active goitrogenic plants, was finely divided, spread out in thin layers, and irradiated with a carbon arc for 20 minutes at a distance of 50 cm. This cabbage was then fed to normal rabbits in quantities yielding 60 calories per kilo per day. Unirradiated cabbage from the same source was fed in equivalent amounts to a similar series of rabbits as a control. All rabbits used in the experiment were injected subcutaneously with 5 mgm of potassium iodide one week

prior to beginning the feeding experiment, to insure complete involution of their thyroid glands. When these animals were killed at the end of the experiment, it was found that the thyroids of those receiving irradiated hashed cabbage had an average weight of 554 mgm, while those of the same number of animals in the control series, which had received non-irradiated hashed cabbage, weighed 248 mgm when averaged. Thus it appears that carbon arc irradiation increases the goiter-producing power of cabbage, probably through a photochemical reaction leading to the formation of the goitrogenic substance.

Cultures of Leukemic Blood Leucocytes By MILA PIERCE, M D (Arch Path, 1932, xiv, 295-322)

By a modification of the Maximow method of tissue culture the white blood cells from a number of patients with leukemia were cultured. These cultures were observed in the living condition, also fixed at six hour intervals or less during the first 24 hours, and at 12 hour intervals or less after that time. After fixation in Zenker's solution plus formaldehyde, they were embedded in celloidin, serially sectioned and stained with a hematoxylin-eosin-azure II solution. Two patients with chronic myelogenous, one with chronic lymphatic, three with myeloblastic, and one with acute lymphatic, leukemia furnished the white blood cells upon the cultures of which detailed observations were made and reported in this paper. In the myeloid and myeloblastic types, myelocytes, polyblasts, fibroblast-like cells, monocytes and hemocytoblasts developed in the cultures. In the chronic lymphatic type, a few monocytes, many polyblasts and fibroblast-like cells appeared, although many of the explanted cells remained unchanged. In the acute lymphatic type, monocytes, polyblasts, fibroblast-like cells and epithelioid cells developed in large numbers, as well as hemocytoblasts morphologically identical with those found in lymphnodes and bone marrow. The unitarian view of the formation of blood cells—that is, that the hemocytoblast or large lymphocyte of the blood and lymphatic tissue is endowed with pluripotentiality as to development, is the theory which

gains the most support from this investigation

Duodenal Ulcer Following Skin Burns By JOHN H. FITZGIBBON, M.D. (Northwest Medicine, 1932, xxxi, 427-430)

Fitzgibbon reviews the literature of duodenal ulcer subsequent to cutaneous burns. This condition was first described by Dupuytren in 1832. Since then many examples have been reported but almost all have been fatal cases, discovered, or at least verified, at the autopsy table. The author's two cases both recovered. In the first, symptoms of duodenal ulcer appeared in the second week after receiving severe burns of the head, neck, and forearms. A few weeks later there was severe bleeding as shown by tarry stools. X-ray examination showed slight distortion of the duodenal cap, which has

since disappeared. The Sippy treatment was rigidly observed for over a year, and recovery has been complete. The second patient also was burned about the upper part of the body, but the diagnosis of ulcer was not made until about five and one-half months after the injury. There was then a distorted duodenal cap. Under medical management there has been progressive improvement. The author considers that this condition is much more common than has been supposed, and that ulceration with symptoms of moderate severity may be overlooked because of the absence of hemorrhage or perforation. The accumulation and study of cases of this group have significant importance in determining the medicolegal status of duodenal ulceration following burns.

Reviews

The Sign of Babinski: A Study of the Evolution of Cortical Dominance in Primates By JOHN F. FULTON, Sterling Professor of Physiology in the Yale University School of Medicine, and ALLEN D. KELLER, Professor of Physiology and Pharmacology in the School of Medicine, University of Alabama. 165 pages, 65 illustrations. Charles C. Thomas, Springfield, Ill., and Baltimore, Md. 1932. Price \$5.00 postpaid.

The preface explains the publication of a monograph on an "isolated neurological sign" and thus disarms criticism on that score. The book is divided into six chapters, an appendix and a bibliography. Babinski's original description of the reflex sign known by his name is followed in order by a study of the plantar reflex signs in the monkey, the baboon, the gibbon, and the chimpanzee under normal circumstances and in conditions of operative experimentation. Then is considered the evolution of cortical dominance while the appendix deals briefly with the general procedures of anesthesia, and a technique of electrosurgical methods

and surgical aftercare. The various experimental protocols are reported with faithful detail. There is ample evidence that the entire research was planned not only with an eye to the elucidation of the problem under immediate investigation but also with a mind open to seize upon such data as may be of value in solving a variety of related neurological problems. Each experiment is briefly summarized at the beginning of its protocol, which makes it possible to read with a greater appreciation. The illustrations are plentiful and serve their purpose well. Some may wish that the authors had allowed themselves a greater latitude in discussing the theoretical aspects of the problems involved, but, after all, the presentation and summarizing of objective data must be the *sine qua non*. Some of the experimental findings could as well have been related to the vexed clinical problem of the "diffuse scleroses" as to the syndrome described by Little. This monograph should have a definite appeal to investigators in clinical and experimental neurology and to neuropathologists.

H. G.

Diseases of the Coronary Arteries (Myocarditis) By DON C SURRON, M S, M D, Associate Professor of Medicine, Northwestern University, Attending Physician, Cook County Hospital, Chief, Cardiac Follow-up Clinic, Cook County Hospital, Chicago, and HAROLD LUETH, Ph D, M D, Formerly Instructor of Physiology, Northwestern University, Chicago 164 pages, 42 illustrations, and 3 color plates C V Mosby Company, St Louis, 1932 Price, \$5 00

In the first chapter of this work, entitled "Symptomatology", an excellent discussion is presented covering not only the symptoms of disease of the coronary arteries, but also the possible etiological factors in acute conditions and the mechanism of the production of symptoms in angina pectoris. Experimental evidences and clinical examples are given to emphasize the various points made. There is also a discussion of differential diagnosis. The latter part of the chapter deals with coronary thrombosis and myocardial infarction. These subjects are covered concisely, omitting little if anything of clinical importance concerning them. The second chapter discusses the physical findings in the arteriosclerotic heart including a moderately long discourse on the electrocardiograms of the various types of heart block. In chapter III a short resume of the anatomy of the heart with regard to its blood supply is given. Special emphasis is placed on the existence of anastomoses among the vessels of the heart which increase in number with age and thereby enable the myocardium to withstand certain vascular accidents. In chapter IV there is a discussion of the pathology of the coronary vessels and the resultant myocardial changes. The opinions of many authors are quoted concerning the nature of these changes, their etiology, etc. The fifth chapter deals with the physiology and pharmacology of the coronary arteries. The first part discusses in some detail the experimental procedure used in studying the flow of blood through these vessels and the effects of various physiologic processes including nervous control upon the rate of flow. The latter portion takes up the effect of certain drugs on the coronary blood flow as determined from animal

experiments. The final chapter is devoted to therapy and gives in a clear, concise manner the latest information on the use of drugs, rest, diet, etc., in the treatment of disease of the coronary arteries. This work is well written throughout and should be of value to the medical student in his clinical years and to the practicing physician.
B M H

Physiology of Bacteria By OTTO RAHN, Professor of Bacteriology, Cornell University, Ithaca, New York 438 pages, 42 illustrations P Blakiston's Son and Co, Inc, 1012 Walnut St, Philadelphia, Pa, 1932 Price, \$6 00 net

It is to be emphasized that *Physiology of Bacteria* by Rahn is not a text in bacteriology. It is above all a study in physiology. In the words of the preface, "It is an attempt to co-ordinate the various simplest functions of life, to study each function in itself and in its effects upon the other functions." The main topics considered are Endogenous Catabolism, Energy Supply of the Cell, Growth, and the Mechanism of Death. The method of development of the subject is logical, giving experimental evidence and applying mathematical analyses to the data obtained. As indicated, only the most fundamental life-phenomena are investigated, and so similar are such life-processes in all protoplasm that the results are in a measure applicable even to man. Well written and well printed, this book should interest the advanced students in both physiology and bacteriology. Careful reading of this book and appraisal of its mathematical analyses will prove a useful exercise for workers in biometric studies in general. To all of these groups it can be fully recommended.

The Expectant Mother's Handbook By FREDERICK C IRVING, A B, M D, Professor of Obstetrics Harvard Medical School Visiting Obstetrician Boston Lying-in Hospital 203 pages 26 illustrations Houghton Mifflin Company, Boston and New York The Riverside Press Cambridge 1932 Price \$1 75

While the average expectant mother finds the Government Bulletin adequate this small book is of course, much more con-

plete and should provide an answer for most of her questions. The subject matter is presented in a concise manner but nothing is slighted and the illustrations, too, are entirely suitable. There is one point that should be brought up to date, as Dr Irving has given the old-fashioned method of diaper folding! From the title of the book the chapter on evolution and heredity was a bit unexpected, but if the reader has no previous knowledge of biology she will learn much of interest to her, and will enjoy the clear exposition of Mendel's Law, even though it is too late to profit by this newly acquired knowledge. The expectant mother will find it altogether worth reading. One can forgive what seems to be a rather unnecessary beckoning of the attention toward the various toxemias of pregnancy including eclampsia—the mother's doctor should watch out for these—when the emphatically reassuring pronouncement denying all significance to maternal impressions and prenatal culture is reached in the final pages.

R C W

Behavior Aspects of Child Conduct By ESTHER LORING RICHARDS, B A, M D, D Sc, Associate Professor of Psychiatry, Johns Hopkins School of Medicine, Physician-in-Charge of Dispensary, Henry Phipps Psychiatric Clinic, Johns Hopkins Hospital. With a Foreword by ADOLF MEYER. 299 pages. The Macmillan Company, New York City, 1932. Price, \$2.50.

From a rich experience and unusual opportunities has developed this sensible book on the behavior problems of children and adolescents. It is characterized by sympathetic treatment and by the common sense simplicity of presentation. It is entirely free from the sonorous nomenclature which

constitutes the professional jargon of so much of the day's applied psychology. This book should be familiar to every pediatrician, neurologist, and general practitioner to whom parents come with problems of "badness" in children. Throughout, the medical aspects are given adequate weight. Numerous well chosen case histories add interest and promote understanding. Some passages approach the epigrammatic: "Better chickenpox and blasphemy than a child established in habits of selfishness inevitably associated with being solitary in all his ways" (See also quotation on page 541).

Die Klinik des Diabetes mellitus im Kindesalter [*Diabetes Mellitus in Childhood*] By Privatdozent Dr F. FREISE and Dr J. M. JAHR. (Reprinted from *Abhandlungen aus der Kinderheilkunde und ihren Grenzgebieten*, Heft 30.) 57 pages, several text figures and two folding tables. S. Karger, Karlstrasse 39, Berlin, Germany. 1932. Price in paper, M. 4.80.

As the title states this monograph treats of the clinical aspects of juvenile diabetes mellitus. About 20 pages are devoted to the metabolism of the diabetic, the significance of protein, fat and carbohydrate for the diabetic organism, and the action of insulin. Further sections deal with the practical application of these principles in diagnosis, with consideration of hereditary and constitutional etiological factors, and with management. Under the latter heading the procedures indicated in the presence of infection and in those cases seen in coma or in a state of hypoglycemia are described. Discussion of the results to be expected from treatment, the prognosis, and a short bibliography conclude the article.

A paper on "Treatment of Pneumonia in Childhood" was presented before the Bradford County Medical Society at Towanda, Pa, July 26, 1932, by Dr William F O'Donnell (Fellow), Clinical Professor of Pediatrics at Georgetown University, Washington, D C

Dr Sinclair Luton (Fellow), St Louis delivered a paper entitled "The Clinical Use of Digitalis", before the recent meeting of the Missouri State Medical Association

Dr Louis Faugeres Bishop (Fellow), and Dr Louis Faugeres Bishop, Jr (Fellow), New York City, had published in the June International Clinics a paper on "Subacute Bacterial Endocarditis", with a colored drawing as a frontispiece, and with other illustrations

On August 1, 1932, Dr Ralph deBallard Clarke, (Fellow), Meriden, Conn, under the auspices of the State Tuberculosis Commission of Connecticut was transferred from Undercliff Sanatorium at Meriden to a more diversified and enlarged field at Laurel Heights Sanatorium at Shelton, Conn

Dr R R Janjigian (Fellow), Wilkes-Barre, Pa, addressed the Luzerne County Medical Society, September 7, 1932, on "Transfusion Problems"

Dr C Ray Lounsberry (Fellow), San Diego, Calif, has been elected president of the staff of the Scripps Memorial Hospital

Dr Guy G Lunsford (Fellow), Millen, Ga, Commissioner of Health for Jenkins County, was recently appointed from the First District, by the Medical Association of Georgia, on a Committee to "Study the Cause of Maternal Deaths and Infant Mortality"

The Jenkins County Board of Health recently sent Dr Lunsford to Williamson County, Tenn, to observe tuberculosis control work being done there

Dr Frederic J Farnell (Fellow), Chairman of the Public Welfare Commission for the State of Rhode Island, is the author of an article entitled, "Development of Mental Health in Childhood", which appeared in the United States Daily, August 6, 1932

Dr Curran Pope (Associate), Louisville, Ky, read a paper on Personal Observa-

tion upon Pyretotherapy, or Fever Treatment" before the Louisville Society of Medicine during July. Dr. Pope also read a paper entitled, "Clinical Studies in Pyretotherapy, or Fever Treatment" before the summer meeting of the Muldraugh District Medical Society at Lebanon, Ky., August 11, 1932.

Dr. Burt R. Shurley (Fellow), Detroit, Mich., in recognition of his service in the American Expeditionary Forces at Base Hospital No. 36, has been cited to receive the "Order of the Purple Heart".

Dr. Russell Richardson (Fellow), Philadelphia, is a member of the staff in charge of clinic service of the George S. Cox Medical Institute for Research and Diabetes at the University of Pennsylvania Hospital. The Cox Institute was opened March 18, 1932.

Dr. Cyril N. H. Long, formerly Associate Professor of Medical Research, McGill University Faculty of Medicine, Montreal, has been appointed Director of the Institute.

Dr. Harry L. Arnold (Fellow), Honolulu, Hawaii, contributed the chapters on the "Physiology of Respiration", "Pathological Physiology of the Thorax", "The Role of X-ray in Thoracic Surgery", and "Therapeutic Pneumothorax", in "Surgery of the Chest" by Dr. George F. Straub.

Dr. Collins H. Johnston (Fellow) of Grand Rapids, Michigan, delivered an address on the Life of Robert Koch, to 300 nurses of Grand Rapids recently.

Dr. William H. Gordon (Fellow), Detroit, Michigan, addressed the Hancock County Medical Society at Hancock, Michigan on September 7, 1932, speaking on the topic, "Agranulocytosis".

Dr. J. A. Myers (Fellow), Minneapolis, Minn., addressed the joint meeting of the Mississippi Valley Conference on Tuberculosis and Mississippi Valley Sanatorium Association, September 12 to 14, 1932, held at Indianapolis, Ind., on "Tuberculosis Infection—Relationship of Tuberculous Child-

hood Infection to the Adult Type of Tuberculosis" and "Tuberculosis As a 'Teen Age Problem'. The Challenge of High School Teachers and Teacher Training Schools".

Dr. Arnold S. Anderson (Associate), St. Paul, Minn., also addressed the above meeting on "Tuberculosis Among Nurses".

Dr. Myers also spoke before the Eleventh Annual Meeting of the West Virginia Tuberculosis and Health Association, September 6-7, 1932, held at Elkins, W. Va., on "Tracing Tuberculosis to Its Source".

Dr. William H. Walsh (Fellow), Chicago, Ill., presented two papers at the Thirty-Fourth Annual Convention of the American Hospital Association in Detroit, September 12 to 16, on "The Relation of the Source of Capital Investment Funds to the Cost of Hospitalization" and "Hospital Planning and Construction—Preliminary Procedures to Assure Economy and Efficiency". These will be published in the 1932 Transactions of the American Hospital Association.

Dr. Salvatore Lojacono (Fellow), Marquette, Mich., was elected President of the Michigan Sanatorium Association at its recent meeting held during August, 1932.

Dr. Leon T. LeWald (Fellow), New York, N. Y., read a paper on "Congenital Absence of Superior Orbital Wall Associated with Pulsating Exophthalmos, Report of Four Cases (Lantern and Motion Picture Demonstration)", before the meeting of the American Roentgen Ray Society in Detroit, September 29, 1932.

Dr. Albert S. Hyman (Fellow), New York, N. Y., addressed the American Congress of Physical Therapy on September 7, 1932, at the meeting held in New York City, his subject being, "Electrocardiographic Control of Diathermic Therapy in Coronary Thrombosis and Angina Pectoris". The paper was discussed by Dr. A. E. Parsonnet (Fellow), Newark, N. J., and Dr. Louis F. Bishop (Fellow), New York, N. Y.

Dr. Hyman was also recently elected Secretary of the Harlem Medical Association of New York, one of the oldest medical societies of the country.

OBITUARIES

DR EDWIN MASSIE BELL

It is with deep regret that announcement is made of the death from bronchopneumonia, of Doctor Edwin Massie Bell, which occurred Saturday, August 20, at George F Geisinger Memorial Hospital, Danville, Pennsylvania

Doctor Bell was born at Lenoir, North Carolina, October 27, 1897, the son of Edwin L. and Elizabeth Massie Bell. His early education was obtained at the Greenbrier Military Academy, Lewisburg, West Virginia. He received his bachelor's degree from Washington and Lee University, Lexington, Virginia, and graduated from the Medical School of the University of Pennsylvania, in 1922. He served in several hospitals in Philadelphia during the next several years and later became Chief Resident at the Episcopal Hospital in Philadelphia. In 1925, tuberculosis developed and he came to Devitt's Camp at Allenwood, Pennsylvania. After a period of rest and recuperation, Doctor Bell was appointed an Associate Physician on the Staff of Devitt's Camp.

Doctor Bell was an ideal physician, having not only a marvelous insight and understanding of medicine, but also of the minds and hearts of his patients and people generally. He possessed the rare faculty of immediately creating a feeling of confidence and security in the minds of his patients, and in their personal problems of life was a sympathetic and helpful counsellor. He possessed rare qualities of friendship and it was said of him that he never gave up a friend. His brilliant

personality, cheerfulness, and lovable qualities endeared him to his associates on the Staff and to hundreds of patients and friends. His philosophy was that no situation in life was impossible, and his ability to create a rational outlook on life in the minds of his patients suffering with tuberculosis was one of his most marvelous accomplishments. Although Doctor Bell's life was comparatively short, it is certain that he accomplished in a few years what it oftentimes takes other men a lifetime.

Dr Bell was a member of the American Medical Association, of the National Tuberculosis Association, and an Associate in the American College of Physicians.

(Furnished by WILLIAM DEVITT, M D, F A C P, Allenwood, Pennsylvania)

DR CHARLES JOSEPH DURAND

Dr Charles Joseph Durand (Fellow), Colfax California died, suddenly, July 6, 1932, following an operation for hernia, aged forty-five years.

Dr Durand was born in Coaticook, Province of Quebec. His preliminary education was obtained at St Hyacinthe's Seminary, St Hyacinthe, Quebec. He graduated from the Medical Department of Laval University, Quebec, in 1911. Shortly after graduation he moved to California because of tuberculosis. For eighteen years he was associated with the Colfax school for the Tuberculous at Colfax California, having served as Assistant

Medical Director for the past fifteen years

Dr Durand was a Past President of the Placer County Medical Society, Past President of the California Northern District Medical Society, a member of the California Academy of Medicine, a member of the California Medical Association, a Fellow of the American Medical Association and a member of the National Tuberculosis Association

At the time of his death he was Medical Health Officer for Colfax, Examining Physician for many years for the Placer Union High School at Auburn, California, and Associate Secretary-Treasurer of the Placer County Medical Society. He had been a Fellow of the American College of Physicians since 1931

Fungus Infections of the Central Nervous System

By WALTER FREEMAN, M D , P H D , F A C P , *Washington, D C*

INVASION of the central nervous system by the higher fungi is a comparatively rare condition, but a number of such cases have been reported during the past few years, especially in America, and it is my privilege to present the results of a comparative study of some twenty-five cases. I take the immediate opportunity of thanking those who have contributed to my collection of pathologic material.

The first cases adequately studied were reported in Germany by von Hansemann and by Turk in 1905 and 1907, although the condition probably was recognized by Zenker in 1861. Curtis, in 1895 and 1896, reported from the Institut Pasteur the case of a young man who developed myxomatous tumors in the groin and lumbar region due to yeast infection and who later succumbed with meningitic symptoms, but necropsy was not performed, so that some doubt must be entertained concerning the invasion of the central nervous system by the fungi. The cases of von Hansemann and of Turk, however, shortly followed by that of Benda, established infection of the central ner-

vous system by fungi upon a firm basis. Only in Turk's case was the diagnosis made during life, although the yeast cells were undoubtedly seen in the sediment of the spinal fluid of all three cases. In Benda's case they were not taken seriously, and in that of von Hansemann the patient was so far advanced in pulmonary tuberculosis that the diagnosis of tuberculous meningitis was made. Cultures were obtained in the cases of Turk and Benda. Turk gives an amusing account of his astonishment upon finding yeasts in the spinal fluid.

Da jetzt jede Verunreinigung vollkommen ausgeschlossen war, musste ich zu der Überzeugung kommen, dass tatsächlich Hefe im Rückenmarkskanale der Kranken vorhanden sei, und dass sie dann eine Bedeutung für die Pathogenese der Erkrankung habe, erschien mir eigentlich selbstverständlich. Ich bat damals sogleich auch den Pathologen unseres Spitals, Professor Kretz, sich einen "verrückten" mikroskopischen Befund, von dessen Herkunft ich ihm gar nichts verriet, anzusehen. Kretz meinte zunächst, ich wolle ihn "aufsitzen" lassen und habe ihm einen drabetischen Harn mit Hefeansiedlung eingestellt. Als ich ihm dann von der Abstammung des Präparates Mitteilung machte, stimmte er meiner Auffassung, dass eine Heferkrankung der Meningen vorliegen müsse, vollkommen bei.*

Presented before the First International Neurological Congress, Berne, Switzerland September 3, 1931. From St Elizabeth's Hospital, Washington, D C. Received for publication, December 15, 1931.

*Now that contamination was fully ruled out, I had to conclude that actual yeasts were present in the patient's spinal fluid and that they were of pathogenic significance in the disease seemed probable. I

In all these cases the involvement of the central nervous system was outstanding and few or no other lesions referable to fungi were found in other parts of the body. Shortly after these reports in the German literature, however, there occurred in Chicago a remarkable series of generalized infections by a different type of yeast-like organism, LeCount being the first to describe in detail the lesions in the central nervous system. Infection of the skin by *Blastomyces* (*Oidiomyces*) had long been recognized. However, in a number of foreign laborers who lived in a mouldy cellar, the superficial lesions were followed by spread of the infection through the body, involving the lungs, bones and internal organs, and sometimes the brain. The skin, however, was always involved and usually presented the primary lesion. Wade and Bell collected the cases in a comprehensive report.

The prominence accorded this type of infection led to confusion, and blastomycosis was only later separated into its different entities comprising torulosis, saccharomycosis and oidiomycosis, chiefly by Stoddard and Cutler. Nearly at the same period, 1909, Evans described involvement of the nervous system by another of the higher fungi, *Coccidioides immitis*, the organism being quite different from those previously described, although the histo-

pathology was in many respects similar. More recently, two other fungi have been reported as invading the central nervous system, namely *Endomyces capsulatus* and a sporothrix. I have studied material from 19 cases of torulosis, and one each of coccidioidial granuloma, oidiomycosis, endomycosis, sporotrichosis, and aspergillosis.

CLINICAL FEATURES

The symptomatology of fungus infection of the nervous system varies to some extent, depending upon the manner of involvement. In some cases the general symptoms of headache, vomiting and stupor betray the general involvement of the meninges and intracranial hypertension, while in others the focal symptoms are predominant. In those cases in which the invasion of the nervous system is secondary to involvement elsewhere, there is usually a focus to be found in the skin, bones or respiratory tract, but in practically all cases in which the nervous system is involved, the predominant clinical features are those connected with the nervous system.

There is usually some record of disturbance in health before the onset of the cerebral symptoms. Certain patients are, as Turk puts it, "zumeist kranklich," suffering from respiratory or digestive symptoms, although indications of cerebral disorder are less common, and mental symptoms are rare. Cutaneous lesions are infrequent in torulosis but are common in coccidioidial granuloma and especially in oidiomycosis. The disease sometimes sets in violently with severe headache, vomiting and vertigo but more often insidiously with pain over the sinuses

then asked Professor Kretz, the pathologist of our hospital to examine a "crazy" microscopic finding, without giving him its source. Kretz thought I was "kidding" him and was showing him a diabetic urine inoculated with yeast. But when I told him of the origin of the preparation he agreed entirely that there must be a yeast invasion of the central nervous system.

or behind the eyes, intermittent at first but later becoming continuous. Stiffness of the neck and neuralgic pains in the limbs and back are commonly mentioned. Staggering and ataxia are seen, with disturbances of sleep, and in some cases faults of memory and irritability that may lead to a clinical diagnosis of organic dementia. Vomiting occurs in

of four in torulosis. Anorexia and vomiting produce an emaciation and debility that may reach an extreme degree. The circulation and respiration are affected only in the latest stages. Moreover the laboratory findings are not characteristic if one excepts the spinal fluid examination. Leucocytosis is mild in most cases, eosinophilia ab-

FIG. 1 Oidiomycosis. Intermediate power view of the lesion in Gaspár's case showing abscesses and giant cells, with a high power view of the organisms.

many cases, without disturbances of the bowels. Failing vision is usually a late phenomenon, diplopia is fairly common, though deafness is less frequent. Hemiplegia is rare in torulosis but is found especially in oidiomycosis. Paraplegia was reported in one or two cases of torulosis but is apparently more common in coccidioidal granuloma.

The general symptoms of acute infectious disease are commonly absent. Fever occurs in cases of generalized oidiomycosis, but only in one case out

of four in torulosis. Anorexia and vomiting produce an emaciation and debility that may reach an extreme degree. The pressure of the spinal fluid is often increased, and the cell count may be numbered in hundreds. On the other hand, the pressure may be normal and the cells little increased. In a few instances there is a complete block. Among these cells, cast-like bodies are apt to be found, sometimes in large numbers. If the organisms are recognized by the alert pathologist the diagnosis is immediately made. Too often,

however, it would seem that the cells are examined under low power or after drying and staining, and are not recognized as fungi. The body cells in the fluid are mostly lymphocytes, although an admixture of polymorphonuclear leucocytes to 30 per cent may be found. Cultures are usually positive. Serologic investigations have revealed no agglutination, precipitation or complement fixation in either human or animal infections. Chemical studies are negative. Animal inoculation may reproduce the cerebral disease.

A number of patients have been subjected to operation upon the suspicion that a tumor might be present. In certain instances the surgeon has recognized the granulomatous character of the process at operation, or the pathologist has reported the finding of the characteristic lesions or organisms in the biopsy specimen. The later course of the disease is almost progressively downward, death resulting in from two to six months. This may be delayed in some instances by repeated lumbar punctures, and only one instance of sudden death following puncture is reported. Provided no intercurrent infection supervenes, the patient usually sinks into coma and dies of respiratory failure.

The clinical picture, then, is usually one of chronic meningitis or cerebral tumor, occasionally suggesting organic dementia of senile or luetic type, but at other times dominated by focal symptoms and signs.

Many varieties of treatment have been attempted, but the mortality in torulosis and in coccidioidal granuloma has been 100 per cent. One case of *oidiomycosis* with meningeal signs re-

covered, and Klarfeld has reported the finding of healed lesions in the experimental cerebral disease. Iodides and lumbar puncture have probably kept patients alive for a period. The extraordinary resistance of *Torula* to aniline dyes makes their use impracticable.

PATHOLOGY

Torula produces a great diversity of pathologic lesions in the central nervous system, while the lesions produced by other varieties of organisms are more or less uniform from case to case. It would appear from comparative mycologic studies now being carried on by Weidman that there are several species of torulae that may invade the nervous system, whereas the causative organisms concerned in the other cases, such as *oidiomycosis* and coccidioidal granuloma, show less variation.

Torula. Three special types of lesions occur in *Torula* infection, meningeal, perivascular and embolic. In nearly half the cases the meninges alone are invaded, although in most cases a few of the organisms will be found in the perivascular spaces close to the surface. The meningitis in such cases is usually nodular and may be mistaken grossly for tuberculous infection. The nodules are described as pale, grayish and translucent, adherent in some cases but easily lifted off in most. Histologically there is a pronounced reaction on the part of the meninges with localized fibrosis, endothelial hyperplasia and giant cell formation, occasionally associated with caseation. Organisms are found in considerable abundance, particularly if a silver impregnation is used. There may or may not be adhesion to the underlying cor-

tex In the cerebellum, however, there is often a granulomatous meningitis that causes marked adhesion of the neighboring leaflets. Inflammatory manifestations in the meninges are fairly marked, with numbers of lymphocytes and occasional plasma cells, but polymorphonuclear leucocytes are never found.

In the other half of the cases there are striking intracerebral lesions. Most of these would appear to be embolic since they are found in the gray matter of the basal ganglia and in the subependymal structures of the midbrain as well as in the cortex. All would appear to originate about the small vessels. Intravascular organisms are seldom found and no occluding clumps. The lesion begins with widening of the perivascular space and multiplication of the endothelial cells. The limiting wall of fibrous tissue is first stretched and then broken, bringing the organisms

into direct contact with the cerebral parenchyma. The reaction to this insult varies from case to case. In some there is tremendous hyperplasia of the endothelial elements with the formation of granulomas containing giant cells and lymphocytes but no leucocytes. The boundaries are usually sharp, but no wall of connective tissue separates the mass from the surrounding parenchyma. In others the lesions become cystic, being ballooned out into more or less rounded structures filled with gelatinous material that does not flow out when the cyst is cut across. Moreover, the cysts are usually multilocular, and when well developed give to the cortex the appearance of soap-suds. There is extraordinarily little reaction about the walls of the cysts in such cases, merely a few endothelial cells swollen to huge proportions by their enclosed organisms, and a feeble reaction on the part of the fibrous tissue of the vascular

FIG. 2. Coccidioidal granuloma. Low power view of the lesion in Rind's second case. The spinal meninges are thickened by a massive granuloma surrounding the cord and compressing the nerve roots.

wall Small vessels with a delicate reticulum of fibrous tissue may be found in the middle of these cysts The interior is filled with organisms and fluid in variable proportions but never with necrotic débris Sometimes these are true yeast tumors, while at other times there seems to have been blocking of the fluid pathways along the vessel with the accumulation of large quantities of fluid and relatively few organisms The trabeculae are made up principally of compressed cerebral parenchyma, and nerve fibres can be demonstrated, as well as a few glia fibrils, but usually no connective tissue In the immediate vicinity of the cysts may be seen compressed nerve cells, considerably distorted, but retaining their staining qualities to a remarkable extent The cysts are evidently formed by the growth of the organisms with resulting compression of the neighboring parenchyma, a fact that was recognized originally by von Hansemann

The reaction on the part of the neuroglia is usually slight or nil, but in one case in which widespread invasion of the tissue had taken place, astrocytes were beautifully demonstrated by Dr Cone, and were present in some profusion (Figure 6) In this same case there was rather marked increase in the number of rod cells in the cortex In most cases, however, there is surprisingly little general reaction to the invasion Fat and iron are practically absent

The embolic lesions in the depths of the brain may reach rather large proportions and are sometimes abundant These present much the same picture as do the superficial lesions, but the trabeculae are apt to be much larger and

often contain numerous connective tissue fibres Moreover there is apt to be slightly more lymphocytic reaction in the vicinity Caseation is not encountered, and there is compression rather than destruction of the neural parenchyma These masses often bulge into the ventricular lumen, and sometimes rupture with scattering of the contained organisms

In a few locations in most of the cases studied there would appear to be invasion of the perivascular space from the exterior although the possibility must be admitted that all the intracerebral lesions originated as embolic foci In one case with very rapid course and sudden termination, large flask-shaped cysts were found communicating with the subarachnoid space by small openings and it would seem that the organisms had gained entrance to the cortex by way of the perivascular ostia and by their growing mass produced the large cavities Moreover, in the brainstem and about the hippocampal region there were found in many cases small areas of perivascular invasion directly beneath the pia, communicating by small openings with the subarachnoid space Since there were no embolic lesions in the cerebral cortex, it would seem that there had been invasion of the perivascular space from without

Invasion of the nerve roots is rather frequent, and the gasserian ganglia have shown lesions in some instances Only once or twice has invasion of the spinal cord been demonstrated

The other organs of the body are affected in more than half the cases Lesions of the lungs preponderate Sometimes the foci in the lungs call attention to the previously unrecog-

nized cerebral invasion, while at other times the existence of well defined ulcerative tuberculosis conceals the lesions of torulosis. Acute military torulosis of the lungs has been reported. The lymph nodes are invaded in some cases, giving the picture of a typical Hodgkin's disease. Ulcerative lesions of the intestine with nodules on the peritoneum have been found in certain cases, the organisms being demonstrated in them. In a few cases there has been generalized infection with foci in the bone marrow, spleen, adrenals, liver and elsewhere, and a positive blood culture during life. Exudates in the pharynx have occurred a few times, and in one case a true ulcerative lesion of the skin occurred, torulae being demonstrated by smear.

On the basis of morphology, the organisms concerned have been grouped

in three types, with fairly good clinical and pathological correlations. The organism is rounded to oval, sometimes convexo-concave, having a mucinous capsule and one or more fatty dots in the interior. It reproduces in the tissues by budding. The size varies from 2 microns to 40. The smallest organism has been separated as a special type since it occurred in a case with rapidly fatal termination and had provoked large flask-shaped perivascular cysts with practically no reaction. The largest organism has been found in a number of cases in which the disease was limited to the meninges and in which the reaction of the mesoblastic elements was the greatest. The intermediate organism, ranging from 5 to 10 microns in diameter, is particularly liable to form intracortical cysts and granulomas as well as to invade the other or-

FIG. 3 Coccidioidal granuloma, Intermediate magnification showing the type of tissue in the granuloma. The giant cells contain organisms.

gans of the body. Cultural studies are useful in differentiating *Torula* from other genera but have not yet differentiated the various species of *Torula*.

Oidiomyces. The effect of invasion of the central nervous system by *Oidiomyces* (*Blastomyces*) is usually quite different from that produced by *Torula*. Only in one or two instances has generalized meningitis resulted, while the meningeal invasion is always present in torulosis. Instead, there are formed lesions considerably resembling tubercles or gummas, usually multiple and sometimes of large size. LeCount reported a mass half as large as the cerebellar hemisphere, and in Gáspár's case a large tumor-like lesion was situated over the surface of the cortex.

Infection of the brain by *Oidiomyces* is apparently always secondary to infection of the skin or lungs, although the primary focus may be hidden. This is in contrast to the condition prevailing in torulosis, where the cerebral infection is apparently primary in most instances. The reports of primary blastomycotic or oidiomycetic meningitis in the literature are probably to be interpreted as torulosis. The Chicago cases were all associated with foci in the skin, bones and lungs. The typical history of such a case was the development of a primary cold abscess of the skin with progressive suppuration and ulceration, later the development of other cutaneous and subcutaneous nodules and painful swellings in various parts. The invasion of the bones gave rise to localized destruction, sometimes with pathological fracture, and the involvement of the lungs, to a picture of chronic tuberculosis. Cerebral symptoms were apparently not observed, al-

though in one or two cases, headache and vomiting gave rise to the suspicion of meningitis. The spinal fluid yielded no specific information. In Gáspár's case a lesion of the brain was found at operation but necropsy was not performed. There were no cutaneous lesions.

Diffuse oidiomycetic meningitis occurred in one of the Chicago cases, but in the others there were multiple nodules resembling tubercles and situated in various locations. In the case reported by Gáspár there was a large grayish mass adherent to the dura and to the underlying convolutions. This was removed surgically but the patient died several weeks later. In contrast to tuberculosis, a blastomycotic tubercle is very firm and rubbery, and has a trabeculated appearance on section with small areas of necrosis.

Microscopically, the essential lesion is a milary abscess that tends to heal with the production of large amounts of fibrous tissue and a central zone of necrosis. This process is repeated over and over again, and in the central portions the fibrous tissue breaks down into caseous material with more or less obliteration of outline. Giant cells are fairly abundant, belonging to the foreign-body type, and they contain organisms. Organisms are found also in the milary abscesses and embedded in the fibrous connective tissue. Infiltration by lymphocytes and plasma cells is quite marked and endothelial cells are abundant. In the older fibrous and necrotic portions of the mass, leucocytes are no longer found, but they are abundant at the margins. There is a tendency toward building up and breaking down of a limiting wall against the in-

vasion process. When the lesion is meningeal there is direct involvement of the cortex, a condition that occurs but seldom in *Toxula* infection.

The organism is rounded, measures from 5 to 10 microns, has little or no capsule, and reproduces in the tissues by budding. It responds best to silver impregnations but can also be brought out by aniline dyes. In ordinary preparations it is unstained but highly refractile and often appears to have a double contour, probably indicating a narrow capsule.

Coccidioides. Coccidioidal granuloma bears a considerable resemblance to oidiomycosis in that the primary lesion is usually cutaneous although certain instances are on record where the meningeal invasion appeared to be primary. The lungs, bones and internal organs often suffer. The invasion appears most often to follow involvement of the vertebrae. In Ryfkogel's case the

cutaneous lesions were followed by a basilar meningitis that provoked hydrocephalus. In the two cases reported by Rand there were focal lesions compressing the spinal cord, one appearing as a dull red firm mass of extradural tissue resembling sarcoma, and the other a grayish sheath investing the upper part of the spinal cord and lower medulla. In the first case the lesion was successfully removed, the patient recovered from the paraplegia and was well some eight months later. The second patient died without operation. Both had evidences of spinal subarachnoid block, and were suspected of having tumors.

The pathologic process is a well-knit granuloma with abundant fibrous tissue and a tendency to the formation of nests of infiltrating cells. Most of these are lymphocytes and fibroblasts, but endothelial cells, plasma cells and leucocytes are occasionally found. Giant cells are numerous, large in size, with

FIG. 4. Coccidioidal granuloma. High magnification showing the process of sporulation in the organism, Perdrau, x 650.

many nuclei, rather irregular after the manner of foreign body giant cells. Necrosis is very slight. The most characteristic feature of the process is the presence of the offending organisms in moderate numbers. These are unmistakable even in ordinary preparations. They range from 10 to 100 microns in diameter, the larger ones showing sporulation, so that one membrane may contain from ten to fifty new organisms. Budding is not seen. Some of them have a double contour, but no mucinous envelope. The smaller ones are often found in endothelial cells and particularly in giant cells. The process in Rand's second case, which I have been privileged to examine, surrounded and compressed the nerve roots but did not penetrate the limiting membrane or involve the neural parenchyma. There was, however, abundant evidence of venous stasis in the cord, with a little perivascular infiltration probably due to degeneration.

Endomyces Only one case of this condition has been reported, but I have seen the sections through the courtesy of Dr. F. B. Mallory. This occurred in a furrier and lasted nearly six months. It began with granulomatous masses in the neck and thigh, headache and disorientation, and was complicated by pulmonary tuberculosis, a positive Wassermann reaction and 5 per cent eosinophilia. The picture of chronic meningitis persisted throughout. At necropsy there were found firm flesh-colored nodules widely distributed in the cerebral meninges. None were found in the interior of the brain.

Histologically, the lesions were circumscribed but not encapsulated, and consisted of very cellular fibrous tissue

permeated with endothelial cells and foreign body giant cells. Lymphocytes and plasma cells were less abundant. Certain areas were necrotic and infiltrated with leucocytes. The organisms were found in the endothelial and giant cells. They were very small, averaging 1.6 microns in diameter, although larger forms were sometimes found. They possessed a small unstained capsule and one to three nucleoids per cell, and they reproduced in the tissue by budding. The mycologic characters of the organism placed it in a new species. It proved pathogenic for animals. The masses in the neck and thigh were of the same causation.

Saccharomyces It is uncertain whether a case of meningeal saccharomycosis has been reported. The case of Curtis was not followed by necropsy, and the organism in Turk's case was probably a torula. Badham reported from Australia a case in which the organism resembled the one described by Curtis, but the pathologic report is too sketchy to be of value, merely indicating that a granulomatous type of meningitis was present.

Sporothrix The only case of sporothrix meningitis is that reported by Hyslop *et al.*, although Dominguez described a case of extradural abscess complicating sporothrix infection of the middle ear. The condition was recognized by finding the spores and mycelia in the spinal fluid, but cultures and animal inoculations were negative. The illness lasted six months with exacerbations and remissions, tetanoid attacks, microptic hallucinations and uncinatiform fits. No infection of the skin or mucous membranes was discovered even at necropsy and the internal or-

FIG 5 Sporotrichosis Low power view of the spinal cord in the case of Hyslop *et al*, showing the moderate meningeal infiltration and fibrosis without necrosis or giant cell formation

FIG 6 Torulosis Intermediate power view of one of the focal embolic lesions of the cerebral cortex showing the hypertrophied astrocytes Preparation of Dr William Cone of Montreal

gans showed no involvement. The base of the brain showed a marked accumulation of cloudy fluid, and between the cerebellar hemisphere was a gelatinous mass, with marked thickening of the arachnoid. A similar condition was observed along the course of the left optic nerve. The condition was limited to the membranes. There was some increase in fibrous tissue with marked infiltration by lymphocytes, plasma cells and endothelial cells. This was particularly pronounced over the cerebellum, the temporal lobe, and the upper end of the spinal cord. Organisms were very difficult to find in the sections and silver impregnation did not demonstrate them. There was, however, a marked discrepancy between the degree of fibrosis observed in the ordinary preparations and that seen by the Perdrau method, so that the fibrillar material observed in the former may have contained some closely packed mycelia.

Aspergillus. Infection of the eye or ear by *aspergillus* is no great rarity, but very few cases of cerebral involvement have been reported. In the case reported recently by Egas Moniz and Loff, a white woman, aged 44, developed iridocyclitis with some inflammation of the vitreous, the cause of which was not determined. After a period of three years in which pain in the eye was the dominant symptom, blindness supervened. There was no headache, but the patient became confused and delirious. The definitive onset was with slowly progressive spastic hemiplegia that terminated in death within three weeks. There was only a terminal rise in fever, mild anemia and no leucocytosis. The spinal fluid pressure was normal, the albumin moderately increased,

the cell count 72 per c mm. Necropsy disclosed no lesions outside of the brain and eye. The meninges were thin. There was a destructive lesion suggestive of a granuloma in the left frontal lobe affecting the internal capsule and the head of the caudate nucleus. The central portion showed marked necrosis, about the periphery were milary abscesses that tended to heal with the production of considerable amounts of fibrous tissue infiltrated with lymphocytes, plasma cells and endothelial elements. Giant cells were numerous, large, and contained many fungi. The fungi were filamentous, branching, rather tortuous and of deep brown color, easily recognized in unstained specimens. Some of them lay free in the exudate of the small abscesses at the periphery. Other cases have been reported, according to the authors, by Ponfick, Arcé, Balado and Franke, Keller, and Orlow. Lacking cultural studies, the identity of the fungus is not certain since it might have belonged to the genus *Penicillium*.

SUMMARY

Invasion of the central nervous system by the higher fungi is characterized clinically by symptoms of chronic meningeal inflammation, sometimes associated with focal signs. Recognizable lesions of similar nature are often absent from other parts of the body, but the finding of the parasites in the spinal fluid establishes the diagnosis. From the pathologic standpoint the lesions are characterized by the formation of granulomata in the meninges and by varied lesions in the brain and cord. *Oidiomyces*, *Aspergillus*, and

Coccidioides provoke miliary abscess formation with tendency to heal, while *Torula* incites very little reaction and sometimes builds yeast tumors and cysts. The common portal of entry is probably the respiratory tract.

Errors in the Diagnosis of Diseases Associated with Jaundice

Observations Based on 533 Cases Verified by Operation or Necropsy

By GEORGE B. EUSTERMAN, M.D., F.A.C.P., *Rochester, Minnesota*

IN this article I have, except occasionally, purposely excluded from consideration cases of icterus neonatorum, or congenital defects of the biliary tract, cases of jaundice the result of obvious hepatotoxins such as arsphenamine, chloroform and arsenic, or of industrial poisons, and cases of septic poisoning, infectious disease, cardiovascular disease, syphilis, decompensated portal cirrhosis, epidemic (catarrhal) jaundice, obvious primary hypertrophic biliary cirrhosis (Hanot), pancreatic cysts, carotinemia and advanced metastatic carcinoma of the liver. The material selected represents a fairly consecutive series of cases which are, to a large extent, representative of the type in which surgical measures for the relief of the jaundice were actually carried out or contemplated.

As in previous contributions, the following factors essential to a diagnosis were stressed: (1) The presence or absence of pain and its character, (2) information as to the patency of the bile passages, especially as shown by a study of the duodenal content, and of

the feces, (3) the van den Bergh reaction in the blood serum, and (4) the determinations of level and variability of the curve of serum pigment. To these may be added the evidence occasionally gained by the cholecystogram, especially in cases of low-grade jaundice not of too long duration, by "scout" films of the gallbladder and bile ducts, and by study of the bacterial and especially the microscopic elements of bile from the gallbladder and extra-hepatic bile ducts.

McNee's simple and practicable classification of jaundice, comprising four groups, obstructive, toxic, infectious and hemolytic, deserves attention. Rich, who has contributed to knowledge of the pathogenesis of the various forms of jaundice, is critical of McNee's classification. He points out that although the first and last divisions of this classification are based on pathogenesis, the second division is based on etiology. Although acknowledging the propriety of Rich's criticism, I question whether he has markedly lessened our diagnostic handicaps by his classification, for in the two main types of jaundice which frequently give rise to difficulty in differential diagnosis, namely, moderate to high-grade jaundice due to disease of the liver itself,

Read before the American College of Physicians, San Francisco, California, April 5, 1932. From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota.

and the more or less painless obstructive jaundice, his laboratory criteria are the same. Moreover, he includes both types in one division, classified as regurgitant jaundice, yet the former is nonsurgical and the latter invariably surgical, and frequently urgently so if irreparable injury to the hepatic parenchyma and vascular structures, and to the biliary tree and pancreas, or even a fatal issue, is to be avoided.

Jaundice is usually a dramatic clinical phenomenon, and although in many instances the causative factor is obvious, too often difficulties attending correct diagnosis are almost insurmountable. Increasing experience adds to a physician's humility, for it makes him cognizant of the various possibilities which may give rise to this condition.

Factors giving rise to difficulty in the expeditious appraisal of many cases of jaundice are as follows: (1) The absence of any trustworthy specific test consistently to distinguish between hepatic and obstructive jaundice (the need for such a test is frequently manifest when the obstruction is incomplete and has developed without painful accompaniment), (2) the association of several lesions, in the biliary tract of the same subject, one of which may give rise to jaundice *per se*, such as stones or calcareous material, or marked biliary cirrhosis, incident to a traumatic stricture of the common bile duct, multiple pigment stones in the gallbladder or common bile duct of the patient with hemolytic icterus, or the occasional association of stone in the common bile duct with carcinoma of the head of the pancreas, (3) pathologic conditions with which it is un-

usual to associate jaundice, and which on occasion may be severe and of long duration, such as calculous cholecystitis, the calculi being confined to the gallbladder, and (4) conditions difficult to recognize clinically and which may produce mechanical jaundice, such as chronic pancreatitis, obliterative cholangitis, benign and malignant tumors of the common bile duct, and especially inflammatory or suppurative lesions of the pancreas.

STONE IN THE COMMON BILE DUCT

Stone in the common bile duct has been the commonest cause of jaundice in my experience and was encountered in 147 of 533 cases. In most cases the stones were multiple, occasionally there were stones in the hepatic ducts. Not infrequently the surgeon noted a single stone confined to the common bile duct or ampulla, or even multiple stones in both. Cholecystic disease is from three to four times as common among women as among men. When the disease does occur in man he is five years older on an average than a woman with the same condition. Conversely, primary carcinoma of the pancreas or ducts is more common among men. In this group of cases of stone in the common duct the sex incidence was about equal, the number was too small for statistical purposes. One-fourth of these patients had submitted to a previous operation, usually drainage or removal of the gallbladder. In cases in which drainage was done a complete external biliary fistula was frequently present. This is invariably indicative of obstruction of the common bile duct, as shown by Balfour and Ross.

In 85 per cent of the entire group a correct primary diagnosis was made of the condition, and an alternative diagnosis in an additional 9 per cent, or in a total of 94 per cent. The chief cause for making an incorrect primary diagnosis (9 per cent) was probably due to the fact that the icterus was mild and transient, or both. Jordan and Weir have shown that almost 6 per cent of the patients with stone in the common bile duct may have no pain at any time, and 13 per cent may never be jaundiced. This incidence might have been even higher if a larger series of cases had been studied. The combination of severe recurring colic, characteristic in most cases, followed by definite icterus, frequently clinical and laboratory evidence of suppurative cholangitis, plus an average moderately elevated and fluctuating level of serum bilirubin explained by the fact that in 91 per cent of such cases the common bile duct is partially patent, is the outstanding clinical manifestation, and is striking enough to account for the high degree of diagnostic accuracy reported in this series. The average value for serum bilirubin was 9.1 mg for each 100 cc of blood. In a similar group studied by Weir, more than 70 per cent of the patients had values of serum bilirubin of less than 10 mg. In a survey of 1,608 surgically verified cases of choledocholithiasis Judd and Marshall observed that if a history is painstakingly obtained and the patient kept in hospital for a period of observation, surprisingly few errors in diagnosis will be made. Bockus and his associates claimed that 86.6 per cent of these cases exhibit evidence of calculus due to the presence of cholesterol crystals and calcium bili-

rubinate pigment in the bile obtained on duodenal drainage. Undoubtedly this diagnostic procedure should be more often resorted to in doubtful cases.

CHOLECYSTITIS WITH STONES

In a series of eighty-five patients with gallstones, who were jaundiced at the time they came under observation, the average serum bilirubin content of the blood was 7 mg for each 100 cc. In 67 per cent a correct primary diagnosis was made, whereas in 30 per cent of the remainder the jaundice was attributed to stones in the common bile duct. From a clinical standpoint this is one of the most interesting groups and seems to be proof of the observations made repeatedly for years by pathologists and surgeons in The Mayo Clinic concerning the association of the liver, pancreas and the extrahepatic biliary ducts in disease of the gallbladder. In sixty-five (77 per cent) of these cases there was gross evidence, at operation, of changes in the organs mentioned. Besides stones in the ducts, compression of the common bile duct from enlarged contiguous glands, and from abscess pockets with marked regional inflammatory reaction consequent to the perforation of stones through the gallbladder, was also noted. Frequently considerable dilatation of the common bile duct was recorded, as though a calculus which had previously obstructed the duct had recently been passed and this conclusion was strengthened by the fact that the patient had experienced colic just prior to operation, followed by icterus, which promptly and progressively began to subside.

Observations made by Hartman in 1,022 cases in which operation was

done in 1922 for cholecystic disease (associated with gallstones in 652 cases) demonstrated that 166 (27 per cent) of the patients, with gallstones and without evidence of choledocholithiasis or other obvious mechanical obstruction of the extrahepatic biliary ducts, gave a history of jaundice of variable degree and duration. Moreover, of 375 patients of this series, who had only chronic cholecystitis at operation, sixty (16 per cent) were having or had had jaundice, 26 per cent of these, as discovered by the surgeon, had pancreatitis also. It is not of so much practical import that the jaundice was erroneously attributed to stone in the choledochus, as it is to remind the surgeon of a history of, or the presence of icterus so that the extrahepatic ducts of the liver and the pancreas will be adequately examined during the operation.

CARCINOMA OF THE PANCREAS

It is usually very difficult to make an unequivocal clinical diagnosis of carcinoma of the pancreas in the absence of jaundice. In a review of 138 cases of this entity in 1922, proved at operation or at necropsy, more than half of the patients, when first seen at the clinic, were without jaundice. In the presence of jaundice the combination of later adult life (average age fifty-six years), recent onset of subjective disturbances and objective signs, infrequency of actual painful seizures or colic, marked and progressive deterioration of weight and strength, high-grade bilirubinemia, with a high, rising, or fairly sustained pigment curve, when associated with palpable gallbladder and repeated absence of bile on duodenal drainage, makes the diagno-

sis fairly easy. Prior to operation, the correct primary diagnosis of carcinoma of the pancreas was made in 84 per cent of sixty-nine cases, and an alternative diagnosis was made in an additional 8 per cent, a total of 92 per cent. In a little more than 30 per cent of cases the duct is partially patent, and in the absence of pain and a palpable gallbladder the condition may be confused with the purely intrahepatic forms of jaundice, or silent stone in the duct. The clinical picture of carcinoma of the pancreas is indistinguishable from carcinomatous tumors of the common bile duct or papilla of Vater, especially in the absence of ulceration, infection and bleeding of the latter.

Complete obstructive jaundice may be caused by stones in the common bile and hepatic ducts, by stricture, by external compression or actual invasion of the common bile duct from carcinoma of the head of the pancreas, by primary carcinoma of the ducts, or by extension of a carcinomatous process from the gallbladder, stomach or duodenum. The pain of obstructive jaundice is chiefly dependent on the rapidity and degree of the obstructing agent. As a consequence there may be instances of stone in the common bile duct without pain, and pancreatic obstruction of the common bile duct with severe biliary colic. The last feature and the coexistence of gallstones in 12 per cent of cases, was responsible for the erroneous primary diagnosis of stone in the common bile duct in 14 per cent of the cases of carcinoma of the pancreas. Intrahepatic jaundice did not figure in the primary diagnosis, which attests to the trustworthy clinical features of the majority of cases of car-

cinoma of the pancreas, but the converse is not true, as will be observed. Of diagnostic and prognostic import, too, are Judd and Counseller's observations on the difference in the effect of benign lesions (stone, stricture) and carcinomatous obstructive lesions on the parenchymatous and vascular structures of the liver as well as on the intrahepatic and extrahepatic bile ducts.

To what extent the quantitative estimation of enzyme activity of the duodenal content is of diagnostic value remains to be seen. In the occasional cases without icterus but with associated occlusion of the pancreatic ducts, the gross characteristics and high fat content of the feces may furnish the first clue to the underlying pathologic change. Of added clinical interest is the occasional roentgenoscopic evidence of involvement of the stomach and duodenum, and rarely of the jejunum. The nature of these observations may be misinterpreted, especially in the absence of jaundice and in the event of obstruction of one of these organs which may occur. One outstanding characteristic of carcinoma of the pancreas is the persistence of jaundice, in contrast to stone in the common bile duct. In only two of many cases of jaundice with carcinoma of the pancreas was the jaundice known to clear entirely. This was the result of secondary ulceration, with temporary opening of the common bile duct and relief of the mechanical obstruction. The highest levels of serum bilirubin are seen in obstructive jaundice due to this lesion and in intrahepatic jaundice. In 75 per cent of a group of cases of obstructive jaundice studied by Weir, there was bilirubinemia of 11 mg, or

more. The average content of serum bilirubin in this series was 17.4 mg.

The following case illustrates exceptions to all rules that might be advanced in differential diagnosis.

A man, aged 72 years, first came to the clinic, February 25, 1932, with the complaint of pruritis of two and a half months' duration. For two or three years he had had some gaseous abdominal distress and bloating. Beginning one year before, he had experienced intermittent discomfort in the right upper quadrant of the abdomen, until three months prior to his admission. About this time, after he had returned from a trip to the mountains, he felt as though his bowels were clogged and took Epsom salts, a chill followed. The next day he had intermittent colic-like pains of moderate severity in the right upper quadrant, lasting for two hours. Two such attacks occurred within the next few days. A physician was not called, but heat was applied locally (hot water bottles) and the pain was relieved. The stools became putty-like, the urine dark, and itching and jaundice followed. During the following month there was no pain, the itching and jaundice gradually disappeared and the stools and urine resumed a normal color. After a brief respite, the icterus, pruritis, biliruria and acholic stools reappeared, but there was no pain. The pruritis was the most disturbing symptom and was present night and day. A week prior to his admission pain had returned for a brief period. The jaundice appeared to be lessening.

Moderate icterus of the sclerae and skin was noted on examination. The patient was comfortable except for the pruritis. There had been moderate loss of weight and strength and the edge of the liver was just palpable. Abdominal masses or tumors were not palpable, and there was no tenderness or rigidity in the right hypochondrium. During a period of observation in hospital the pruritis persisted, it was somewhat relieved by gynergen (ergotamine tartrate) administered orally thrice daily. Duodenal drainage always produced a free flow of clear amber bile, which contained a small amount of calcium bilirubinate pigment, but no cholesterol.

crystals or other abnormality. The feces contained bile, but no occult blood. The serum bilirubin fluctuated from an initial value of 58 to 21 mg for each 100 cc of blood. Coagulation time (Lee) was somewhat prolonged. There was moderate secondary anemia. The urine was free from sugar on repeated examination, but following the intravenous administration of glucose, in preparation for operation, glycosuria and hyperglycemia were evident. A galactose tolerance test was negative. The concentration of urea rose from 44 to 62 mg for each 100 cc of blood. The carbon dioxide combining power of the blood plasma ranged from 46.6 to 53.2 per cent by volume. "Scout" films of the region of the gallbladder plainly showed the silhouette of a distended gallbladder, apparently filled with bile. From time to time the patient experienced considerable pain in the right upper part of the abdomen, but never acute enough to justify the use of an opiate.

March 17, laparotomy revealed a carcinomatous tumor of the head of the pancreas. One week later the patient succumbed to hemorrhage and bronchopneumonia. Necropsy revealed that the carcinoma partially compressed the lumen of the common bile duct.

A history of pain was not obtainable at the outset, perhaps on account of the age of the patient and his fatigued, toxic state. The condition on this account was regarded as an intrahepatic form of jaundice, because of temporary resolution of the icterus, its long duration, the patency of the duct, as determined by duodenal drainage, the low level of serum bilirubin, the absence of palpable gallbladder, negligible microscopic examination of the bile and negative galactose tolerance test (2.4 gm of sugar in the urine, normal more than 2.5 gm). The latter test may be negative during convalescence from infectious or long continued jaundice. On the other hand, the recent onset of jaundice in an elderly patient,

its persistence, evidence of disturbed carbohydrate metabolism following the administration of glucose, suggesting injury to the pancreas by the factor that caused the jaundice, and the eventual admission of recollection of attacks of pain favored surgical exploration for what appeared to be obstructive jaundice from either stones or a new growth.

In contrast to this patient was one in a nearby bed, a man fifteen years younger, with marked, more or less painless, jaundice of five weeks' duration, but without pruritis, an average level of serum bilirubin of 17.5 mg and a definitely enlarged, movable, insensitive gallbladder. In addition, duodenal drainage for bile was repeatedly unsuccessful. All of the evidence in the latter case was characteristic of carcinoma of the pancreas, a condition which was confirmed at operation.

A palpable, distended gallbladder is of great diagnostic significance, and it is probably present in most cases of obstinate jaundice due to carcinoma of the head of the pancreas. Recently it has been found advantageous to administer intravenously from 3 to 5 grams of pentobarbital sodium (sodium ethyl 1-methylbutyl barbiturate) if there are no direct contraindications. Prompt and complete relaxation of the abdomen is thus secured, which greatly facilitates examination of a resistant abdomen. In this manner it is possible repeatedly to palpate a distended gallbladder, as well as the pancreatic neoplasm, itself. This drug is preferable to sodium amytal (sodium isoamyl ethyl barbiturate) as the patient recovers more promptly from the effect of the anesthesia.

STRICTURE OF THE EXTRAHEPATIC BILE DUCTS

Benign stricture of the common or hepatic bile ducts, or both, as a cause of jaundice, does not loom large in medical literature, but the surgeon of wide experience is familiar with it, and it represents one of the most difficult of all problems in abdominal surgery. My series comprised sixty-seven cases, in which a primary correct diagnosis of the lesion was made in 63 per cent. In an additional 15 per cent, or a total of 78 per cent, an alternative preoperative diagnosis was recorded of stricture of the duct. The chief incorrect primary diagnosis (28 per cent) was that of stones in the common bile duct. This was to a certain extent unavoidable as in 24 per cent of the cases there were stones or stony material in the common bile duct or gallbladder, or both. The average level of serum bilirubin was 11.23 mg and occupied a position between that in cases of stone in the common bile duct and in carcinoma of the pancreas. This midway position is also true relative to the patency of the ducts, as in about 80 per cent the stricture was partially patent. In all but four cases operation had been performed for removal of the gallbladder. In one case cholecystostomy and drainage of an abscess had been done. In the three cases in which operation was not performed, the stricture was obviously due to obliterative cholangitis. In a careful review of preoperative and postoperative data, the impression was gained that the stricture was directly the result of surgical trauma to the duct. Judd has, on several occasions, described the conditions under which

trauma is sustained and how it may reasonably be avoided. Too often trustworthy clinical or laboratory evidence of pre-existing cholecystic disease was conspicuous by its absence, and this would vitiate the contention that the cholangitis present before cholecystectomy had persisted and progressed, and was the eventual cause of the stricture. As a consequence this complication should be suspected if evidence of extrahepatic obstruction of bile ducts follows removal of the gallbladder, especially if these phenomena are painless in onset and were not present before operation was undertaken. Many of the symptoms and eventual complications of traumatic stricture are common to stone in the duct, such as colic, pruritus, jaundice, chills, fever, and external biliary fistula, but the circumstances attending the inauguration of these symptoms is of direct diagnostic import. Variation in symptoms is due to the injury sustained, the nature and degree of repair when attempted and to the rate and degree of eventual obstruction and hepatic injury. In addition, bile stasis which is the result of stricture tends to cholangitis and the formation of stones or stony concretions. The latter sometimes obtain in the presence of rubber tubing used for anastomosis. In an attempt to differentiate stone in the common bile duct and stricture of the duct, certain clinical features are of relative importance. In case of stricture, symptoms invariably develop sooner after operation. In case of stone in the duct symptoms disappear on an average of three years and eight months after operation. The same is true of jaundice. There is a lower incidence of colic in cases of

stricture (about 30 per cent) in the absence of coexistent stone, whereas in the presence of stone, colic occurs in as high as 80 per cent. There is a higher incidence of pruritus in cases of stricture. Immediate postoperative jaundice, or persisting external biliary fistula, is suggestive of stricture. As a rule the flow of bile is scantier than in cases of stone in the duct and low fixed curves are invariably the result of biliary cirrhosis. Periods of increased bilirubin in the serum are concomitant with episodes of intermittent obstruction. It must be remembered that colic or jaundice, or both, following cholecystectomy, may supervene because of a stone in the duct which was overlooked even in the absence of calculi elsewhere, and stones have formed at varying intervals years after removal of a cholecystic gallbladder without stones.

CONGENITAL AND ACQUIRED HEMOLYTIC ICTERUS

The combination of clinical and laboratory data makes possible an accurate preoperative diagnosis in all of these cases. This series consists of thirty-eight patients, 58 per cent of whom were females. One-third of the patients were aged less than ten years. Thirty-four per cent had chronic cholecystic disease, eleven of the thirteen having calculous cholecystitis. With few exceptions the van den Bergh reaction remained indirect. The average level of serum bilirubin was 4.5 mg. in each 100 c.c. In several cases the initial test showed normal fragility which somewhat confused the issue temporarily, but which on subsequent examinations revealed the characteristic increased

fragility of the erythrocytes to hypotonic salt solution. The combination of low-grade icterus, secondary anemia, microcytosis, enlargement of the spleen, the youth of the patient in many instances, invariable indirect reaction even in the presence of gallstones, and the increased fragility of the erythrocytes, is characteristic of the disease, and makes possible an unequivocal diagnosis. There were no cases in this series of the characteristic pigment stone in the common bile duct, to produce associated obstructive jaundice. The results following splenectomy were universally excellent, and all but two of the patients survived the operation.

INTRAHEPATIC JAUNDICE

This generic term is applied to cases of diverse etiology in which the jaundice is the result of a disease process confined to the liver itself, in contrast to jaundice arising from mechanical obstruction of the extrahepatic bile ducts, from whatever cause. The series consists of thirty-five cases, in which twenty-six patients were submitted to operation. It is comprised chiefly of twenty-five cases of portal and biliary cirrhosis, hepatitis and subacute yellow atrophy, the latter followed cinchophen hypersensitivity or toxemia. In five of the cases gallstones were also present, in three cases the stones did not produce symptoms. A correct primary diagnosis was made in 54 per cent of the cases, and an alternative diagnosis in 14 per cent or a total of 68 per cent. The disease was chiefly confused with stones in the common bile duct (26 per cent) and carcinoma of the pancreas (17 per cent).

As previously stated, the highest readings for bilirubin are seen in cases of malignant obstruction and intrahepatic jaundice. In both instances the onset and course of the disease may be painless. This also applies to a small percentage of cases of stone in the common bile duct. Persistent absence of bile on duodenal drainage favors complete obstruction from carcinoma of the pancreas, impacted stone in the duct, or other mechanical factor, yet in the early stages of acute infectious or toxic hepatitis, or in certain stages of acute, severe types of hepatic jaundice, there may be temporary suppression of biliary excretion, or possibly obstruction to larger ducts by plugs of mucus, with similar negative results from duodenal drainage.

If patients are young the painless jaundice is invariably the result of infection or hepatotoxins, such as cinchophen, arsphenamine, oxyiodide and arsenic, and bacterial toxins of certain tropical diseases. If patients are elderly the diagnosis of catarrhal jaundice in the absence of endemic jaundice or obvious hepatotoxin, is usually erroneous. McVicar and Fitts felt that the cases of painless jaundice and a high degree of serum bilirubinemia offered the greatest difficulty in diagnosis. Weir, on the other hand, pointed out the great obstacles to successful distinction between hepatic forms of jaundice and obstructive jaundice if the obstruction is partial, and he stressed the need for some specific test especially if the obstruction has developed without the accompaniment of pain. To this end the galactose tolerance test has been employed whenever indicated and estimations made of the value of cho-

lesterol in the blood and cholesterol esters in an attempt to distinguish between obstructive and intrahepatic jaundice. The diagnostic value of the galactose tolerance and cholesterol tests will be appraised in the near future. As regards the former it promises to be of considerable value in the clinical differentiation of the painless or intrahepatic and obstructive forms of jaundice. In the first type in which as a rule the parenchyma is definitely injured, the galactose tolerance test is usually positive. However, in cases of long duration and in infectious jaundice during the convalescent period, the galactose tests may give negative results. Not infrequently positive results may obtain in obstructive jaundice, especially in cases of pancreatic carcinoma. At present one gets the impression that a positive result always signifies hepatic injury, but the injury may not necessarily be primarily hepatic. A negative test does not necessarily exclude an intrahepatic form of jaundice.

The practical aspects of the problem are obvious. One should not temporize in the presence of obstructive jaundice from whatever cause, if the surgical risk is not too great. Neither should one subject the patient to unnecessary, often hazardous operation if the evidence favors the nonobstructive form. The element of time under close observation in hospital is often a prime factor in successful differential diagnosis.

PRIMARY NEOPLASMS OF THE EXTRAHEPATIC BILE DUCTS

In this series were twenty-five cases, in all but two of which carcinoma was present. There were two benign tu-

mors, one a neurofibroma and the other an adenomatous cyst, both involving the common bile duct. In this series also there was a preponderance of males (68 per cent) and the average level of serum bilirubin was 16 mg. With the occasional exception of an ulcerating tumor of the papilla of Vater, or of the ampulla projecting into the duodenal lumen, this condition is indistinguishable from carcinoma of the pancreas if lesions are low in the duct, the condition may also perfectly simulate stone in the duct. Because of this fact and the comparative rarity of the lesion under consideration, in no instance was a primary correct diagnosis made, but an alternative or secondary diagnosis of carcinoma of the common bile duct was recorded in 20 per cent. An erroneous primary diagnosis of carcinoma of the pancreas was made in 52 per cent, of stone in the common bile duct in 44 per cent, and of stricture of the common bile duct in 4 per cent.

Marshall reviewed the cases in the clinic observed during a period of twenty years, ending January 1, 1930. There were forty-nine primary carcinomas of the common bile ducts, and four benign tumors. Three-fourths of the patients were aged more than fifty years, the male sex predominating. In 53 per cent of the cases disease of the biliary tract was associated, and in 43 per cent of these there were stones in the gallbladder or common bile ducts. This coincidence would partly account for the frequent diagnosis of stone in the common bile duct. The most common site of the new growth was in the lower end of the common bile duct or ampulla. The tendency to remission or intermittency of jaundice is more pre-

valent in cases of carcinoma of the common bile duct than in cases of carcinoma of the pancreas, but in a little less than half of the total number of cases cited by Marshall, the jaundice was extreme, constant and progressive. There may be complete absence of pain in a third of the cases. The lesions are small as a rule, metastasis is uncommon and late, technical surgical difficulties may be as insurmountable as the diagnostic difficulties, and widespread symptoms, with severe inflammatory and septic sequelae in ducts, liver or portal vein, are present sooner or later.

CARCINOMA OF THE GALLBLADDER

There were seventeen patients in this series, females predominating. The average age was similar to that in the series of neoplasms of extrahepatic bile ducts, and all were advanced in the fifth decade of life. The average value of serum bilirubin was 15.7 mg, the jaundice being due largely to extension of the process into the ducts and liver, or there was compression of the ducts by involvement of the lymphatic nodes at the hilum, or of nodes along the common bile duct. As there are no characteristic symptoms or signs of this neoplasm, a primary correct diagnosis, especially in the early, favorable stage, is rarely made prior to operation. The one exception in this series was a case in which exploration had recently been performed elsewhere. A primary erroneous diagnosis of cholelithiasis or choledocholithiasis was recorded in 59 per cent, and of carcinoma of the pancreas in 35 per cent. The invariable presence of stones in the gallbladder, cholecystitis or cholesterosis, often makes logical the diagnosis of stone in

the common bile duct, as noted, when jaundice supervened, whereas extension of the process into other organs, representing an advanced condition, with corresponding deterioration in general health, would make logical the primary erroneous diagnosis of carcinoma of the pancreas in another group. Jaundice would tend to obscure the diagnosis rather than help to clarify it.

Carcinoma is frequently found in the gallbladder in the absence of jaundice. The earliest and most favorable cases are those in which histopathologic examination after removal of the gallbladder for chronic calculous or noncalculous cholecystitis, reveals carcinomatous changes in the viscus hitherto unsuspected. Another more advanced condition without jaundice, presents the following symptoms and signs in varying combinations, which should raise a suspicion of carcinomatous changes in the gallbladder. An antecedent history of repeated colic over a variable period of time, distressing gaseous indigestion of a chronic, recurring nature, gradually, or suddenly superseded by symptoms of a constant, less severe nature, with that progressive deterioration in weight, strength and appetite characteristic of carcinoma, an enlarged or nodular liver with retention of dye confirming metastatic involvement, and actual or apparent enlargement, firmness and moderate tenderness of the gallbladder. To the absence or marked impairment of function often are added cholecystographic evidences of calculi.

ACUTE AND CHRONIC PANCREATITIS

In this series of fifteen cases there were twice as many males as females.

The age incidence of both sexes fell within the fifth decade, and the males were four years older, on an average, than the females. Diagnosis in this group was based on the history, surgical findings in the pancreas in the absence of other marked gross changes in liver and extrahepatic bile ducts, and eventual good recovery following operation. This latter feature is of significance because it is extremely difficult at times for even the most experienced surgeon to determine from palpatory evidence the exact nature of the pathologic process in this organ. All of the cases were chronic, with one exception, and this patient had an acute gangrenous appendix. The average value of serum bilirubin was 7.5 mg. In no instance was a primary correct diagnosis of chronic pancreatitis made, but in the acute case an alternative correct diagnosis was recorded. In the chronic group were cases of stone in the gallbladder and common bile duct (80 per cent), or carcinoma of the pancreas (13 per cent). In four of these cholecystostomy had been done for the removal of stones, and in several others there were pathologic changes in the gallbladder, in one stones were present. In one case a pancreatic type of diarrhea developed which was treated successfully. In this group, and in the group of malignant lesions in the absence of jaundice, the diagnosis is extremely difficult.

CHOLECYSTITIS WITHOUT STONES

There are seven cases in this series, a smaller incidence than in the series reported by Hartman. The average value of serum bilirubin was 8.1 mg., and in no instance was a correct diag-

nosis made. A diagnosis of calculous cholecystitis (57 per cent), or of choledocholithiasis (43 per cent) was made. There was evidence of associated lesions in the liver, pancreas or common bile ducts in five cases, and in one case the anamnesis and the dilated appearance of the common bile duct at operation made one strongly suspect that a stone had recently passed through the duct. All the patients recovered. One of these cases could have been classified with the preceding group.

MISCELLANEOUS CASES

There were twenty-eight cases in this series, and a variety of entities of infrequent occurrence are included. In cases of jaundice with generalized intra-abdominal carcinoma, the primary source of which could not be determined at laparotomy, gastric carcinoma with metastasis to the liver or common bile ducts, and cholangitis, constitute half of the entire series. It is likely that the pancreas and gallbladder are frequently the site of primary origin. Primary carcinoma of the duodenum, and primary sarcoma and carcinoma of the liver continue to be rare entities, in my experience.

The result of the study of the whole series is summarized in table I.

SUMMARY

Factors giving rise to great difficulty in the successful and expeditious diagnosis of cases of jaundice, under certain circumstances are reviewed.

The most common cause of jaundice

in the cases studied was choledocholithiasis. The most uncommon cause was primary carcinoma of the liver. Error in diagnosis in the former was infrequent (6 per cent).

Calculous cholecystitis without stones in the extrahepatic bile ducts was the second most common cause of jaundice. Correct diagnosis was made in 67 per cent. The chief incorrect previous diagnosis was choledocholithiasis.

A correct primary and alternative diagnosis of carcinoma of the pancreas was made in 92 per cent. The diagnosis of carcinoma of the pancreas in the absence of jaundice is usually exceedingly difficult.

Postoperative traumatic stricture of the extrahepatic bile ducts was the fourth most common cause of jaundice. A correct primary or alternative diagnosis was made in 78 per cent. The chief incorrect primary diagnosis was choledocholithiasis.

The diagnosis of congenital and acquired hemolytic icterus was made preoperatively in 100 per cent. Certain clinical and laboratory data make possible an unequivocal diagnosis in the typical cases.

Primary carcinoma of the gallbladder or extrahepatic bile ducts and chronic pancreatitis, especially in the absence of demonstrable cholecytic disease in the latter were not often diagnosed correctly prior to operation or necropsy.

Intrahepatic forms of jaundice are frequently erroneously diagnosed as choledocholithiasis or carcinoma of the pancreas.

TABLE I
Element of Error in Diagnosis of Jaundiced Patients (533 Cases)

Peptic Ulcer

Early and Late Effects of Parenteral Injections of a Nonspecific Protein: Conclusions Drawn from Experimental Work on the Modus Operandi of the Therapeutic Agent, and on the Etiology of the Lesion Helped by It

By LAY MARTIN, B S , M D , F A C P , *Baltimore, Maryland*

INTRODUCTION

SEVERAL years ago I reported to the American Gastro-enterological Association on a small series of cases of peptic ulcer¹ They had been treated only by means of parenteral injections of milk from which fat and bacteria had been removed Since that time I have followed, with some interest, similar cases and it is now possible to report on a larger series and also upon the duration of relief in the cases so treated

In the preliminary paper I gave an exhaustive review of the literature on the subject Very little has been added to our knowledge since then, so I shall not go further into the matter except to mention the work of Leon Schiff which was reported before the Ohio State Medical Association² during the Spring of 1930 He reviews a series of cases, 27 in number, which have been treated quite similarly to those which I reported upon¹ His results are also quite definite although he obtained complete relief in a smaller per cent of cases—

66 per cent complete cure and 85 per cent complete or partial

METHOD

Ninety-five patients with the history, signs and symptoms, and the roentgenographic and laboratory evidence of peptic ulcer were given intramuscular injections of milk protein* This series included only cases in which the diagnosis was as well established as is possible without biopsy Observations extended over a period of four and a half years Seventy-nine white men, twelve colored men, two white and two colored women were included in the series The ages varied between 21 and 78 years

The patients were allowed to continue on the diet they had been taking prior to their admission into the clinic Therefore, the great majority of them were retained on a regular routine of life because they were also allowed, with few exceptions, to continue in their regular occupations

Control roentgenograms were always used After these were obtained the patients were given their first dose of the nonspecific milk protein Films were

*The nonspecific milk preparation used was Aolin

From the Gastro-intestinal Division of the Department of Medicine of the Johns Hopkins University Received for publication January 16 1932

obtained at the end of treatment. We have in some of the first patients obtained plates many months after the series of injections.

Gastric analyses were obtained before the control films were taken. In the first series of reported cases the gastric acidity was rechecked after some months, as no regularity was observed in the changes of secretion, this check has been largely eliminated.

In the past two and one-half years treatment has consisted of six intramuscular injections of the nonspecific protein on alternate days. If the symptoms were rather slow in decreasing, more than six injections were usually given. The amount used at each injection was always 10 c c.

OBSERVATIONS

The first change noticed in the signs and symptomatology of duodenal or gastric ulcer, following injection treatment is the disappearance of pain. This usually is noted after the second or third injection. Rarely does pain last after the fifth or sixth. It is surprising to see the change of facial expression even in the most chronic cases. Other symptoms such as vomiting, distension, gas, belching, and regurgitation disappear later. A number of the men came in doubled up with pain. The great majority were relieved. Naturally the same amount of relief is not obtained in all cases. However, the large proportion of the patients show a gratifying immediate relief.

In the preliminary paper data were given on roentgenographic changes at various periods after the first injection. At first I had been led to believe that it might be possible to obtain immediate

visualization of decrease of spasm. Films taken one-half hour after the first injection and at the end of the treatment, at a time when in the majority of cases there had been no symptoms for several days, showed little if any changes. Films taken from two to eighteen months after the end of treatment frequently did, however, show definitely less spasm. Occasionally a smaller defect was seen, but in most cases no change was noted.

Films have been obtained on 34 cases two to three years after treatment. Twelve of the cases show a marked improvement as judged by roentgenographic views, others, however, show very little if any deviation from the controls. All cases showing roentgenographic improvement are without symptoms. Three showing only diminution of spasm are clinically well. Some of the patients who are clinically well still have undoubted roentgenographic evidence of ulcer.

The results of treatment on gastric secretion have been reported in detail in the preliminary paper. The conclusion is reiterated: "The immediate and late effects were decidedly different. In the first group, there was an increase of gastric acidity in five of the seventeen cases, an approximate constancy in nine, and a true decrease in three. Of these twenty-one patients, eight were observed after a period of from four to eighteen months. In this group there was an increase of acid in two, an approximate constancy in two and a true decrease in four."

To see any general discomfort follow the injections is a rarity. In five cases there was acute dyspnea with a feeling of suffocation and fright. This was

not accompanied by any marked change in the strength of the pulse and lasted but a few minutes. It was probably due to a leakage of some of the fluid into a vein. To prevent this occurrence the following technic has been worked out. An imaginary line is drawn across the buttock between the anterior superior spine and the sacro-iliac junction. The midpoint of this line is usually situated two to three inches below the crest of the ilium. The needle is inserted by a bold stroke at this point, obliquely downward. Care must be taken to see that it is not in a vein. There are no large veins in this area and I have seen no unpleasant reaction since using this method of injection.

In four cases there has developed local inflammation and swelling of the buttock, similar to an Arthus phenomenon, after the third or fourth injection. In one case a giant urticaria developed eight days after the primary injection. The patient had been receiving injections on alternate days.

It is not an infrequent occurrence to have the patient complain of epigastric pain on the evening of the day on which the injection is given. Constipation is usually associated with the treatment, so much so, that laxatives are given routinely. When occult blood was found in the stools the cases were always followed to note the time of its disappearance. All patients having good results soon presented stools negative to the benzidine test.

I am well aware of the difficulties in the way of making a diagnosis of marginal ulcer after a gastro-enterostomy. In four of the patients such a diagnosis seemed justified. Three of them made excellent immediate recoveries.

Occult blood, which was present in two, soon disappeared. Two of the cases of marginal ulcer had been under strict medical surveillance for some time without relief of symptoms. Under nonspecific treatment both made excellent clinical recoveries.

There have been a number of patients who have relapsed after one series of injections. Most of these can be helped by another course of injections. This is of importance in that group of patients on whom for a variety of reasons, surgery is contraindicated or declined. These may be kept comfortable by repeated courses of the nonspecific treatment. It is especially beneficial in those cases in which the time of recurrence can be guessed by a consideration of previous history. When it is given before this time attacks have been aborted or prevented.

In table I all of the cases have been analysed under two main headings: results noted at the end of treatment and again one to four years after the end of the first treatment. In the latter group several of the patients had been given more than one series of injections and these are grouped under a subheading. Of the 95 patients, 71 received treatment over a year ago and it has been possible to interview 60 of them. Those who received treatment in the past six months have not been analysed for final results. A study of this table shows the interesting fact that the *immediate results* of treatment are superior to the late ones. It also brings out the same relation between the value of treatment and the length of pre-treatment symptoms.

a 84.6 per cent of the patients having had symptoms only a few

TABLE I

The Relationship of Immediate to Late Results Following Nonspecific Protein Injections
Also the Value of Treatment in Relation to the Duration of Symptoms
Prior to Institution of Treatment

		RESULTS AT END OF ONE SERIES OF NONSPECIFIC PROTEIN INJECTIONS			RESULTS 1 TO 4 YEARS AFTER NONSPECIFIC PROTEIN INJECTIONS		
Pretreatment duration of symptoms in years		0 to 1	1 to 5	5 or more	0 to 1	1 to 5	5 or more
Number of cases		26	50	19	18	31	11
PERCENTAGE OF CASES	I Clinical cures	73.1	72.0	52.6	50.0	45.2	36.4
	a With one series of injections	73.1	72.0	52.6	38.9	19.4	9.1
	b With two or more series of injections				11.1	25.8	27.3
	II Improved	11.5	2.0	10.5	27.8	6.5	18.2
	III Unimproved	15.3	26.0	36.8	22.1	48.4	45.5
	IV Coming to operation				11.1	38.8	27.3

months showed rapid clinical cure or improvement

b 74.0 per cent of the patients having had symptoms one to five years showed rapid clinical cure or improvement

c 63.1 per cent of the patients having had symptoms five years or more showed rapid clinical cure or improvement

When we consider the efficiency of treatment instituted one to four years ago in relation to the length of pre-symptoms we note

a 77.8 per cent of those having had symptoms only a few months are still clinically cured or definitely improved

b 51.7 per cent of those having had symptoms for five years or more are clinically cured or definitely improved.

c 54.6 per cent of those having had

symptoms for five years or more are clinically cured or definitely improved

Another point is worthy of note—the cases of long duration of symptoms as a rule require more series of injections than those having had symptoms for but a short time

In order not to over-accentuate the effects of the injections it is well to examine the tables for the relationship between the percentage of clinical cures and clinical improvement one to four years after institution of treatment. Here it may be seen that there is a drop in the number of cases retaining clinical cures in relation to those obtaining complete relief at the cessation of the first series of injections. On the other hand the number of cases which showed clinical improvement alone is greater than in the corresponding group at the end of the first series of injections

DISCUSSION

The classical peptic ulcer gives rise to a series of regularly recurring attacks which come on two, three or four times a year, frequently limited to the Fall and Spring. Each attack is self-limited and during the periods of remission entire good health returns. It is known that the early ulcer of little penetration heals entirely and leaves no scar. As the attacks increase in number or severity, a scar is formed which remains during the periods of remission but which may cause no symptoms. However, in time many extrinsic factors such as secondary inflammation, stenosis, nervous derangement, anatomic or pathologic changes may and usually do cause secondary symptoms which are confused with those of the original ulcer. In fact, it may be that the entire syndrome of the patient is due entirely to these secondary changes.

Considering the mode of onset, the duration of symptoms, the self-limitation of an attack, and the regularity of recurrence, it seems entirely logical to believe that the original ulceration, erosion or congestion may be the result of a reaction of sensitized tissue to a specific antigen. Therefore, the ulcer *per se* is simply an allergic phenomenon.

If this hypothesis be true it would seem quite likely that we were desensitizing the body against some unknown antigen. Certainly the suddenness with which the signs and symptoms disappeared after the institution of non-specific protein therapeutics via parenteral injection led one to think strongly of this possibility. Consequently the following investigation⁴ has been carried out.

Guinea pigs were sensitized to egg albumen. At various intervals during the development of sensitization (taken as two weeks) different groups were injected with a varying number of doses of intravenous mercurochrome or intramuscular milk protein or both. Each group was controlled with a similar or larger number of pigs. At the end of two weeks all the pigs were given the minimum effective dose which killed a large majority of the control animals. It was found that the agents listed above had the ability to protect a certain proportion of the test animals against death and very frequently against even light to moderate shock. To be effective, the last desensitizing dose must not be given more than 24 hours before the shocking dose. The results may be seen in table II.

Guinea pigs injected intradermally with emulsions of whole bacteria both alive and dead (*Pneumococcus* Type I, *Streptococcus hemolyticus*, and *Staphylococcus aureus* 209) developed sensitization to the same antigen in the remarkably short period of 48 hours. The skin sensitization lasted for at least a month but by that time had diminished. The strongest sensitization was developed ten days after the primary inoculation. Table III gives the results.

Guinea pigs were given intradermic injections of 0.2 cc milk protein in one flank, practically simultaneously with 0.2 cc virulent *Pneumococcus* Type I on the other flank. Twenty-four hours later the milk protein injection was repeated but in a different spot on the same flank. At forty-eight hours the initial injections were repeated but in new areas. Controls were run which

did not receive milk protein Twenty-four hours after the second injection of pneumococcus antigen, there was marked skin reaction in the control animals There was a very much smaller or no reaction in the test animals The difference in the phenomenon may be seen in figures 1 and 2

More recently we have made the interesting observation that it is possible to obtain marked allergic response in the duodenum Guinea pigs were anesthetized with ether By laparotomy 0.1 c.c. of horse serum was injected into the anterior wall of the duodenum The animals were sewed up and placed in clean cages They soon recovered from the effects of the operation and behaved in a normal manner A control series was given 0.1 c.c. of horse serum intraperitoneally Two weeks later the animals were shocked with a minimum lethal dose of horse serum, the dose was determined upon the controls and given into the jugular vein Four pigs which had received injections within the wall of the duodenum, were not given the shocking dose, they were

held as additional controls and killed with ether along with those pigs which survived the minimum lethal dose At autopsy the intraperitoneally sensitized and subsequently shocked guinea pigs showed no lesion in the duodenum The four pigs which had been sensitized within the wall of the duodenum but not shocked showed no lesion in the duodenum Those pigs which had been sensitized within the wall of the duodenum and then given the minimum lethal dose of horse serum showed local areas of congestion in the duodenum and the first portion of the small intestine, in every pig there was a clearly defined engorgement and in some pigs it was quite severe

It seems to us that this may well explain the origin of certain duodenal ulcers

We are now undertaking investigations to determine the possibility of desensitizing the duodenum by the parenteral injection of milk in the somatic musculature

The work on desensitization of both types, specific and nonspecific, points

FIG 2 Test animal which had received three intradermic injections of milk protein during period of sensitization Marked diminution in skin response to reinjection of heated pneumococcus type I 48 hours after initial intradermic injection with living pneumococcus type I (From Bull Johns Hopkins Hosp, 1930, xlv, 256)

to the conclusion that the period of desensitization is but temporary and in the nonspecific type it is of short duration. Therefore, if it is true that our results in the treatment of peptic ulcer are due to nonspecific desensitization it will not lead one to expect a cure for a long period of time. Also it should be kept in mind that this form of treatment will have very little, if any, effect against the secondary characteristics of peptic ulcer. It is impossible to expect any relief in the face of a true cicatricial formation which is causing obstruction. On the other hand several cases with partial obstruction have been either clinically cured or improved. In these cases the obstruction must have been due to edema or spasm (secondary results of the ulcer).

Adhesions about, and distortion of the pylorus and duodenum are common secondary changes and no help is to be expected when the signs and symptoms are coming from such a condition.

There are cases, proven at biopsy to be only uncomplicated ulcers, in which the treatment has been of no avail. The obvious explanation in these cases would seem to be that the milk protein had no desensitizing ability.

The German clinicians feel strongly that the beneficial results obtained by this method are brought out by the reaction or shock which follow the intravenous injection of a foreign protein.

As shown above a reaction of such a type in the series is produced only by accident and from the results obtained it seems unnecessary to accept such an hypothesis.

The present method of treatment consists in five to seven injections on alternate days. Depending upon the

type of ulcer and the secondary changes in the stomach, more are sometimes given. Several patients have noticed that a weekly or biweekly injection over periods of weeks will greatly diminish their symptoms. They, however, remain only improved and never become clinically cured, usually they become bored or discontented and drift away.

One of the strongest factors in suggesting this method of treatment lies in the economical side. All but four of the patients were ambulatory, practically all continued with their work and remained on a more or less general diet. I have, however, somewhat changed my views on the latter condition and attempt to keep them on food simpler than they usually consume.

The question of dosage is important. The most satisfactory results have been obtained by giving six or more intramuscular injections of 10 c c each of the nonspecific protein preparation on alternate days. If an Arthus phenomenon or serum sickness develops, treatment must be discontinued or the dosage reduced below the reacting level. At times it is possible to desensitize the patient by slowly increasing the dose, at other times none can be given, another form of nonspecific protein may give excellent results.

There is no doubt of the value of the therapeutics, the results given in table I are quite convincing. The desirability of instituting treatment as soon as possible is definitely shown. Many of the cases had been on a medical treatment for a long time without any benefit being derived therefrom.

In the present light of our knowledge, with the specific antigen or antigen unknown, with the fact that non-

specific desensitization lasts for only a short period of time, it would seem wise to change in some ways the method of treatment carried out in this investigation

- a If the patient presents himself early when the recurrences are appearing at regular times, it would be best to attempt to give a series of injections before the next attack is due. The percentage of clinical cures would most probably be increased. Since good results have been obtained by soft foods, it seems sensible to institute and continue on a white meat, vegetable puree and stewed fruit diet for a considerable period of time and certainly before the next attack is expected to arrive.

If ulcers start as areas of congestion and hyperemia, a soft non-irritating diet may prevent ulcer formation.

- b If the patient presents himself with well marked secondary changes the type of diet outlined above is absolutely indicated. In this manner, food is much more easily transferred through the distorted area and the work of the stomach lessened.

These changes are suggested because

I believe that a greater percentage of the patients will continue the immediate improvement or clinical cure into the group of late results.

SUMMARY

- 1 Intramuscular injections of milk protein have been given to 95 patients suffering from peptic ulcer.

- 2 Of these patients 78 per cent had been greatly improved or clinically cured at the end of treatment. At this time a greater percentage of those whose symptoms had existed for only a few months are clinically cured or improved, that is 84.6 per cent.

- 3 One to four years after treatment 60 per cent of the 60 cases who reported were clinically cured or improved. Of those whose symptoms had existed less than one year prior to treatment 77.9 per cent were improved or clinically cured.

- 4 The majority of these patients had been on a general diet.

- 5 Evidence is advanced that duodenal ulcer in man may be the result of a reaction of sensitized cells to a specific antigen.

- 6 Evidence is also advanced that the therapeutic aid brought about by the parenteral injection of milk protein may be due to a nonspecific desensitization of the sensitized cells.

The Clinical Diagnosis of Pulmonary Arteriosclerosis

By HENRY L. ULRICH, M.D., F.A.C.P., *Minneapolis, Minn.*

PULMONARY arteriosclerosis is rather a broad term given to a variety of changes in the pulmonary arteries. Anatomically three types of sclerosing processes are recognized. Atherosclerosis, a senile process which begins rather late in life in the lesser circulation, is always found after 70.¹ It is a part of the generalized atherosclerosis found in the greater system. It is of no particular clinical importance. There are exceptions to that statement. Again, atherosclerosis is found earlier in the pulmonary system accompanying the other two types of sclerosis respectively. Arteriosclerosis in the sense of Jores² is a compensatory phenomenon in which there is a proliferation of the intima and media and in which there is usually involvement of the arterioles. Then there is the inflammatory sclerosis in which syphilis is a specific etiological agent. The French lean toward other infective agents,³ particularly emphasizing the virus of rheumatism. Moschowitz³ insists true arteriosclerosis is always due to in-

creased vascular tension. When found in the pulmonary arteries it is always due to either primary hypertension in this system or is due to increased capillary resistance secondary to mitral disease, congenital heart disease, vascular disease (syphilis), or to increased resistance secondary to diminished capillary beds, as seen in emphysema, chronic inflammatory processes in the lung and pleura, or kyphoscoliosis. Whatever the etiological antecedent, and whatever the variety of changes, if it has clinical significance, there is always associated an enlargement of the right heart. This fact, the right-sided hypertrophy, is of great importance. It is the central corridor for the approach in a diagnostic sense. It is the pivotal fact in making a silent condition swing into a clinically discernible one. For, as this hypertrophy continues, it reaches a stage of imbalance. Decompensation occurs and the latent pulmonary phase enters the cardiac phase—called the "black cardiacs" or sometimes erroneously termed Ayerza's disease. It would be better to call this stage Ayerza's syndrome. The usual diagnosis at this stage is "mitral disease" or "congenital heart" or, if there is a history of pulmonary symptoms, the findings in the lungs may cloak the underlying vascular changes.

From the Medical Service of the University Hospital and the Department of Medicine, University of Minnesota, Minneapolis, Minn.

Presented before The American College of Physicians at the San Francisco Meeting April 6, 1932.

Generally speaking, up to 1900 pulmonary arteriosclerosis was a moment of postmortem surprise. Beginning with this century, various observers have claimed a clinical recognition of the condition. Ayerza and Airillaga⁴ in Argentina, Posselt⁵ in Germany, Rogers⁶ in India, Eppinger and Wagner⁷ in Austria, Laubry⁸ in France, Coombs⁹ in England, and a good many others have voiced an antemortem diagnosis and emphasized the possible frequency of its existence.

A tentative schema of the grouping of pulmonary sclerosis is seen in table I. The symptomatology is based on the emphasis placed by the various observers. The symptoms of the acute processes are more or less hypothetical. The French recognize a primary, acute arteritis in the pulmonary system. The acute secondary type must be due always to infection in the right heart and as a rule manifests itself as mycotic aneurysms of the vessels.

Briefly, the clinical bases for the diagnosis of pulmonary arteriosclerosis have been. A delimitation of a heart which resembles a mitral or congenital type, the symptoms of an undue cyanosis and dyspnea not at all commensurate with the clinical findings, repeated

hemoptyses with little evidence of infarct, radiologically, a silhouette of the heart of a mitral or congenital type, with increased hilus shadows, increased vascularity, and visible pulsation of the larger, and sometimes pulsation of the smaller, vessels in the lung field.

A typical schema for diagnosis is given in table II, which gives Posselt's criteria for pulmonary sclerosis associated with mitral disease. To this, I have added a supplementary criterion of Laubry's,⁸ table III, which illustrates the French school of approach and adds considerable radiological minutiae not known at the time of Posselt's writings.

It must be recalled that with the inception of the cardiac phase, progressive cardiac symptoms manifest themselves. By the simple expedient of finding no, or very little, evidence of congestive failure at the base of the lung, when clinically there is a large liver, evidence of ascites and edema, the diagnosis of primary pulmonary sclerosis can be established. This may also be the clinical dividing line between the primary group and the secondary group (table I). In the secondary class the mitral group can be selected from the primary and from

TABLE I
PULMONARY ARTERIOSCLEROSIS

1 Primary No heart lesion	{	a Acute	Hemoptysis—pallor—picture of septicemia or infection
		b Chronic	Hemoptysis, cyanosis (black cardines) picture of mitral or congenital heart—no evidence of congestive failure in the lungs, or very little
2 Secondary	{	a Acute	Mycotic—infection
		b Chronic	Essentially one of heart disease. Hemoptysis with very little evidence of mitral
			Clubbing of fingers rare
			Lung findings present when lung lesions are associated

TABLE II
POSSILT'S CRITERIA (1908) WITH MITRAL STENOSIS

- 1 Physical findings
 - a Increased dullness to the left of the upper sternum and neighboring areas—with pain on pressure or percussion over this area
 - b Exceptionally spreading of heart dullness to the right
 - c The appearance of the pulmonic bulge by X-ray examination
 - d Gradual wandering of apical noises, systolic, presystolic, toward the pulmonic area
- 2 Clinical symptoms
 - a Striking cyanosis, an early sign and long standing compared with the amount of dyspnea or in its absence, or with the amount of stasis or edema
 - b Attacks of dyspragia intermittens angiosclerotica pulmonalis (angina hypercyanotica)
 - c In spite of high grade cyanosis, absence of clubbing of fingers
 - d Repeated hemoptysis without outstanding evidence of infarct

TABLE III
LAUBRY'S CRITERIA (1926)

- Clinical symptoms
- Easily provoked dyspnea
 - Repeated and tenacious bronchitides
 - The repeated appearance of hemoptysis
 - Hemoptysis is more important than cyanosis—which last is more discrete or absent at this stage (early)
 - The cyanosis must be extricated from all other causes capable of producing it and particularly tuberculosis
- Objectively
- Abnormal prolongation of the second sound
 - The persistence of a reduplication with accentuation of the second pulmonic
 - Finally the evidence of a pulmonic soufflé This when present indicates an abnormal distention of the arterial wall
- Radioscopic evidence (fluoroscopic) (Chaperon)
- Two prominent syndromes
- I Venous stasis—characterized by
 - a Increase of hilus shadows whose contours are vague and impossible to define in the inferior portion where the pulmonary veins are lost in the lung fields
 - b By the paradox of an abnormal visibility of the right bronchus
 - c An abnormal bulging of the right auricle
 - d When the pulmonary stasis is pronounced by a diminution of clarity of the lung fields
 - II Arterial hypertension
 - a By an elongation and bulging of the middle arch
 - b By an increase in volume of the pulmonary hilus made up radiologically in the greater part by the arteries whose contours are distinct, easily traceable and whose contractions are copious and more visible
 - c Sometimes by a series of dark trails easily followed throughout the lung fields, animated by contractions like at the hilus and belonging like them to the arterial fields
 - d The phenomenon of the dance of the hilus—only seen twice—possibly due to inflammatory reactions in the hilus

the congenital heart and the heart of chronic inflammatory disease of the lung by the esophagogram. The congenital group and chronic inflammatory group can be differentiated from the others only by their histories, and by the chronic changes in the lungs.

Up to now we have been attempting to diagnose the pulmonary arterio-

sclerosis by the old standards. To these methods I have added an entirely new triad of findings which clinically aids materially in calling attention to the changes in the pulmonary vessels, besides affording a much more accurate and earlier impression of this condition, long before the Ayerza phase has supervened. See table IV.

TABLE IV

A NEW TRIAD FOUND IN CASES WHICH CLINICALLY FIT INTO THE CATEGORY OF
PULMONARY ARTERIOSCLEROSIS

- 1 Palpable pulsation in the intercostal spaces
- 2 A pulmonary souffle heard all over the chest
- 3 The dance of the diaphragm a fluoroscopic finding which consists in a down and up movement of the diaphragm synchronously with systole and superimposed on its respiratory movements

This triad is based on the assumption that, with increased arterial pressure and with the usual accompanying dilation in the larger and medium sized vessels, the increased volume of blood, with increased force, entering the lung would make the lung pulsate as a whole very much like the expansile pulsation of a congested liver in tricuspid insufficiency, or like the pulsation of a liver in aortic insufficiency when there is a marked water-hammer effect in the hepatic arteries. In a case of mitral disease which under the fluoroscope had exquisite pulsation of the pulmonary arteries well out in the lung areas, palpation of the interspaces gave a distinct impulse, not as strong as that felt at the apex but definite enough so that students were able to feel it. This impulse is best felt in the second interspace to the left and right of the sternum, laterally in the interspaces in the mid-axillary lines, and posteriorly in the lower interspaces. Sometimes it can be felt in the interscapular areas. If this were true it occurred to me that there might be a vascular bruit due to the deformity of the pulmonary vessels. This proved to be so in this test case. The bruit is vascular, it must be differentiated and disassociated from cardiac noises transmitted by the chest wall. This bruit is heard all over the chest but can be most clearly heard in the left second interspace, in the right second interspace, and over the whole

right side, particularly since the cardiac noises are less heard on that side. This bruit resembles the noise heard over a placenta, or over a highly vascular and enlarged spleen or pulsating liver. Again it was argued that if a lung pulsated as a whole to the extent that it was palpable through the chest wall it might be possible to see this effect on the diaphragm. Again this case revealed this phenomenon. Under the fluoroscope, particularly on the right side, following a deep breath, the down-and-up movement of the dome can be seen during expiration, synchronous with the heart beat. This movement was called the dance of the diaphragm. In some cases the above technic is not necessary. The dance is seen in either phase of respiration.

The radiologist found two cases with pulsating vessels which gave the above triad of findings. The clinician picked up two on physical examination and predicted the radiological findings of pulsating vessels, also the dance of the diaphragm, both of which were confirmed by the radiologist. The significance of these findings in aiding us in the diagnosis of pulmonary artery disease is apparent.

ILLUSTRATIVE CASES

The following cases are reported which illustrate (1) the variations in the arterial lesions (2) the manner of death and (3) the older clinical ap-

proach None of these had applied to them the test of the new diagnostic triad The reason for this is simple—it was not known at the time

Case I A woman, age 31, following the birth of her child four years before, complained of weakness and dyspnea There had been swelling of the feet, ankles and abdomen the last six months There had been occasional blood-streaked sputum For two years she had been hoarse Her family history is negative Her own gives a record of malaria She has been amenorrheic for two years She had been diagnosed mitral disease with coronary insufficiency Her physical examination gave the usual evidence of congestive failure with more cyanosis than usual and no evidence of moisture at the bases of the lungs In the interscapular area on the left at the level of the third spinous process there was a visible and palpable pulsation and a marked systolic bruit Radiologically the silhouette showed massive right-sided hypertrophy, a marked pulmonic bulge, and enormously dilated pulmonic arteries at the hilus which were seen to pulsate under the fluoroscope There was increased hemoglobin and red cells The Wassermann test was negative The electrocardiogram showed right preponderance A diagnosis of congenital heart disease with patent ductus arteriosus was made, the physical signs in the interscapular area being considered corroborative evidence

Postmortem, the case presented the usual signs of congestive failure The heart weighed 425 grams The hypertrophy was confined to the right ventricle which showed extreme hypertrophy and dilation No changes were noted in the valves The foramen ovale was not open and there was no indication of the presence of a ductus arteriosus The coronary and the root of the aorta were smooth The root of the pulmonary artery was also smooth

The right lung weighed 400 grams Crepitation was present throughout There were no pleural effusions but there were a few areas of slight consolidation in the apex The pulmonary artery valves opened well and to the right of the root of the aorta

intimal thickening The thickened areas were arranged in spots, particularly about the orifices of the branches of the artery The pulmonary artery was extensively dilated It had a large caliber far into the lung in its many branches On section, microscopically, a few active areas of tuberculosis were found in the apex The small arteries showed a marked intimal thickening which had the appearance of being proliferative in character, the lumina of many of the small arteries were almost completely closed In the larger arteries there was a marked atheromatous condition The left lung weighed approximately the same as the right and showed a similar condition in the pulmonary vessels

Comment This was a beautiful case of primary pulmonary arteriosclerosis Being our first case, we were led into the usual error of calling it a mitral or congenital heart disease (See figures 1 and 2)

Case II N J, female, age 27, complained of dyspnea, edema of legs, and prolonged uterine bleeding Her family history was negative The patient has had weakness on exertion since she was 15 years old Three years ago there was hoarseness and the sputum at times was blood-tinged Physical examination on two admissions gave the following data Heart enlarged to the right and left, and a mitral murmur The chest was clear, the liver down There was pitting edema of the extremities There was marked cyanosis, and a dark brown pigmentation over the face, mouth, extremities and body Laboratory examination Hemoglobin, 108 per cent, red blood cells, 5,000,000 plus, white blood cells, 15,000, polymorphonuclears, 80 per cent Stool and urine examinations were negative The basal rate was normal The Wassermann test was negative Blood pressure 90/80 to 160/100 X-ray studies showed a massive right heart, no esophageal displacements, no pulsation of the pulmonary vessels, or any involvement of the lungs Electrocardiogram showed right preponderance A diagnosis was made of mitral disease, congenital heart, Ayerza's disease The patient died in convulsions

Postmortem findings The heart weighed 360 grams. The left auricle and ventricle were normal, the right auricle and ventricle were greatly dilated and showed moderate hypertrophy. A careful search was made for anomalies, but none were found. The pulmonary artery was dilated, apparently larger than the aorta. The tricuspid and pulmonary valves were enlarged. The root of the aorta was smooth except for an occasional yellowish plaque.

The right lung weighed 430 grams, the left 315 grams. There was a moderate, yellowish sclerotic thickening of the larger branches of the pulmonary artery. There was dilation of some of the middle-sized branches. The veins were normal. There was

an old Ghon tubercle beneath the pleura of the right lower lobe. The aorta was small and smooth. Many sections of the lung examined for evidence of sclerosis of the arterioles proved negative.

Comment This case was a clinical replica of the first. The points of similarity were (1) weakness and dyspnea over a long period, (2) cough with sputum at times hemorrhagic, (3) cyanosis with increased hemoglobin, (4) pigmentation, (5) decompensation *without evidence of congestive failure at the base of the lung*, (6) vocal cord involvement, (7) massive enlargement

FIG 1 Gross specimen of lung of Case I, showing atherosclerosis and dilation of large vessels

of the right heart, (8) pulmonary artery dilation, (9) evidence of previous or present tuberculosis. The difference lies mainly in the pulmonary artery. The first case had peripheral arteriolar sclerosis with dilatation and atherosclerosis of the larger vessels. The second had dilatation of the larger vessels with some sclerosis, but the peripheral vessels were normal. In the first case the hypertrophy of the right heart can

Case III L. K., age 65, female. This patient led an active life. There is a history of asthma and bronchitis for many years. For three years there had been progressive heart failure with no response to any type of therapy. Edema was controlled for a long time by ammonium nitrate and salyrgan. The diagnosis of pulmonary arteriosclerosis was made by exclusion because of the progressive character of the failure, the marked cyanosis and the lack of evidence for coronary disease. There was edema, ascites, enlarged liver, but the lung bases were clear, that is,

FIG 2 Obliterating sclerosis of arteriole in periphery of lung, Case I x300

be easily explained by the increased arterial tension. In the second case we must explain the right-sided hypertrophy on some other basis. I venture the following. The loss of elasticity in the dilated vessels threw an extra burden on the heart which caused its hypertrophy. This does not apply particularly on the left side. There are many compensatory factors on the left side which do not obtain in a simple system like the lesser circulation.

until fluid appeared toward the end. There was radiological evidence of old healed tuberculosis of the lung with old pleuritis.

At postmortem examination the heart weighed 575 grams. There was hypertrophy of both ventricles, with marked dilatation of the right auricle and ventricle. The coronaries were sclerotic but patent. The aorta showed marked sclerosis extending to the ilia. There was marked sclerosis and dilatation of the pulmonary arteries. On microscopic section the peripheral vessels of the lungs showed sclerosis also.

Comment. Occasionally one finds

sclerosis in both systems. Here the extensive change in the pulmonary vessels was striking. The sclerosis might be considered as a senile process. In any event, the *factor* of the sclerosis of the pulmonary vessels with the dilatation is strongly emphasized as a cause of heart failure in this case.

*Case IV** J. S., male, 73. This patient gave a history of onset with an acute respiratory infection with cough, fever and pain in the chest which rapidly subsided. This was followed by attacks of dyspnea and edema of the extremities. These symptoms continued for two years, when he entered the hospital with a particularly severe attack.

*Previously reported by Dr. A. R. Hall of St. Paul, at the Minnesota Academy of Medicine, 1927. I again thank Dr. Hall for permission to use this case.

of dyspnea and cyanosis. His temperature was normal, the heart sounds were clear. A diagnosis of asthma and bronchitis was made. The patient died suddenly.

At postmortem examination the heart weighed 710 grams. The left ventricle was slightly enlarged. The right ventricle was much enlarged in size. There were no anomalies, acquired or congenital. A thrombus was present in the pulmonary artery, 3 cm. above the pulmonic valves. This thrombus was old and organized and on this a fresh thrombus occluded the vessel completely. All the branches of the pulmonary artery were occluded with thrombi attached to their walls and the vessels appeared thickened throughout. Microscopically the vessels showed marked hypertrophy of all the coats. The vasa vasorum were dilated and filled with blood, giving the appearance of an attempt at collateral circulation. The smaller vessels showed obliterating sclerosis.

FIG. 3. Thickening of vessel walls and organizing thrombus in a vessel of moderate caliber. Note the reaction in the vasa vasorum. Case IV. x60.

Comment This case is included because of the age of the patient and the manner of death. Complete occlusion of the pulmonary artery by a thrombus is not common in arteriosclerosis of this vessel.

The following four cases are very briefly detailed with silhouettes because they represent a group in which we have applied the new triad as well as the old criteria in coming to the conclusion that we are dealing with pulmonary arterial disease.

Case I Female, age 26, entered the hospital for a minor orthopedic operation. She gave a history of repeated attacks of tonsillitis but not rheumatism. There had been attacks of cardiac embarrassment since her fifteenth year. A diagnosis of mitral disease

was made, which was verified by X-ray (figure 5), including a positive esophagogram. Under the fluoroscope the pulmonary vessels were seen to pulsate far out in the lung fields. It was on this case that we worked out the triad of physical findings.

Clinical diagnosis Mitral disease with pulmonary arteriosclerosis.

Case II I S, female, age 14 (Figure 6). There was a history of whooping cough at 5 weeks (?) from which 9 months was required for convalescence. At 3 years she had scarlet fever with kidney involvement. Heart symptoms were noted at 5 when she had smallpox. She began school at 6, at 8 she was easily fatigued on slight exertion. She had had several periods of long rest in bed. Briefly her physical examination showed some cyanosis, varying cardiac noises, *lungs clear*. Her X-ray findings showed a congenital type of heart with pulsating pulmo-

FIG. 4. Proliferation and edematous thickening of the intima of a much smaller vessel. (G. & V. 734)

FIG 5 Teleoroentgenogram of Case V Typical mitral configuration The oesophagogram was positive Cardiac condition Mitral stenosis

FIG 6 Teleoroentgenogram of Case VI Note enlarged heart with typical pulmonary bulge The oesophagogram was normal No cardiac condition

nary vessels in the lung fields. In attempting to find our triad in this child, she gave beautiful evidence of pulsation of the intercostal spaces, an exquisite pulmonic souffle and, under the fluoroscope, the dance of the diaphragm.

Clinical diagnosis Primary pulmonary arteriosclerosis.

Case III M. N., male, 12 (Figure 7). This boy had a severe bout of rheumatism. There was a pancarditis. The pericarditis and effusion were very severe. There was a slow recovery with restoration of normal blood findings and weight but the tachycardia persisted. He likewise exhibited our triad of findings. The pulsation of the vessels and the dance of the diaphragm were predicted in his case by the clinician.

Clinical diagnosis Mitral disease, adherent pericardium, pulmonary arteriosclerosis.

Case IV Female, age 24 (Figure 8). There was a history of the diagnosis of a

congenital heart lesion for 12 years. Since that time the patient has lived a restricted life. There were weakness, dyspnea and cyanosis. Lungs were clear. The heart was not much enlarged, there was a typical thrill and systolic murmur at the second interspace. This patient likewise gave the evidence of increased pulmonary circulation according to our physical tests. At the first thought one would wonder how stenosis would permit the factor producing sclerosis to operate, furthermore, with stenosis how the physical signs found in the chest in this case were possible. In answer to this question I can only state that Posselt¹⁰ in his 127 cases of pulmonary arteriosclerosis found 4 with pulmonary stenosis.

Clinical diagnosis Pulmonary stenosis, pulmonary arteriosclerosis.

Comment With the evidences of a mitral or congenital heart and the rad-

FIG. 7. Fluoroscopic view of Case VII. Note the enlargement of the heart in both directions. The chestogram showed the characteristic impingement due to a dilated left ventricle. Cardiac conditions, rheumatic heart, mitral stenosis, adherent pericardium.

iological evidence of pulsation of the pulmonary vessels, and the corroborative evidence of this new triad of findings, it is reasonable to assume that we are dealing with increased arterial pressure in the pulmonary vessels. And, furthermore, that, with such increased pressure, changes in the vessels have occurred which can be included in the clinical diagnosis of pulmonary arteriosclerosis.

SUMMARY

A new triad is added to the old criteria for the diagnosis of pulmonary arteriosclerosis. With this new triad an earlier diagnosis of pulmonary arteriosclerosis is possible—long before the cardiac phase has been reached. Dilatation with consequent loss of elasticity of the pulmonary vessels may be a factor in the right-sided hypertrophy.

FIG 8 Teleoroentgenogram of Case VIII showing the typical pulmonic bulge. Oesophagogram normal. Cardiac condition pulmonary stenosis.

demic proportions and reached its height in the Sacramento Valley between July 11 and 20. Although cases were seen throughout California, serious outbreaks were reported principally from the Sacramento Valley and Southern California. Localized outbreaks have been observed in Nevada and Arizona. For a week or two the malady would rage in a certain section, then subside only to reappear in the same district. It is of interest that the horses of most of the farms, which had one or many cases of encephalomyelitis during 1930, remained well in 1931 despite the fact that they were located in districts which suffered heavily during the most recent epidemic. As a rule only one horse in ten showed symptoms of the disease in the 1930 outbreak and rarely more than one or two animals of a group became affected. However, during 1931 higher proportions than this occurred. Thus on one ranch, five of twenty-two animals were infected, on others seven of eight (6 deaths), three of nine, and five of fourteen respectively were observed. This peculiarity has been explained on the hypothesis that many horses contract the disease in such a mild form that it is not recognized. Again with the onset of cooler weather, in October, 1931, the disease disappeared. A non-official but cooperative canvass among practicing veterinarians in the stricken districts elicited a total of 2,416 cases. Supplemented by additional reports from various other sources it is estimated that early in 1931, 5,580, or 25 per 1000, of the horse population contracted the disease. The average mortality was 47 per cent. Therefore during 1930 and 1931 approximately 6,000

horses succumbed to a form of encephalomyelitis which is apparently identical with the so-called "cerebrospinal meningitis" reported from various parts of the United States during the past 70 years. In the west Central States this infection caused heavy losses in 1912 as the so-called "Kansas-Nebraska horse plague". It has frequently been confused with "forage poisoning" and "equine botulism". During the past 2 weeks (March, 1932) reports have been received that the disease is again active in the San Joaquin Valley and in Southern California and it is anticipated that with the onset of warm weather the infection will reappear in epidemic form.

Stallions, as well as geldings and mares, and suckling colts, even aged horses, are susceptible. As a rule only animals kept on farms in more or less cultivated districts have contracted the disease. Nothing definite is known relative to the spread of the disease from farm to farm or how it is introduced into a community or why it occurs in *periodic cyclical* recurrences in extensive outbreaks within a year. Since the virus circulates in the blood, the rôle of flies or other biting insects deserves experimental consideration. In many ways, the equine malady shows a behavior analogous to human infantile paralysis. It is therefore not unlikely that the spread is due principally to unrecognized carriers. However, the infection may possibly be carried by food or water which has at some time been contaminated by the carriers or the diseased animals. Certain technical difficulties have thus far rendered a search for carriers impractical.

CLINICAL SYMPTOMS

The period of incubation in the spontaneously contracted disease is difficult to estimate although a few observations indicate a lapse of from one to three weeks between exposure and readily recognized symptoms. Under experimental conditions and especially with massive intracerebral infection the incubation time is on the average eight days and may be as short as three days.

Preceding the onset of the acute symptoms which attract attention, the temperature is found to vary from 37.2° to 41.1° C. Unwillingness to be led, lack of spirit, slightly incoordinated gait, abnormal position of the limbs, failure to respond when called, or in unbroken colts, failure to run when approached are some of the premonitory signs which may rapidly be followed by more pronounced manifestations of the disease.

In severe cases, the horses stagger, fall and are unable to get up when pressed to do so. They may lie on their sides. Convulsive or swimming motions are common and cause, as a rule, severe bruising of the head and limbs. In the advanced stages, the animals are relatively quiet. The pulse and respiration are usually accelerated and towards the end arrhythmic. Cutaneous hyperesthesia of the neck may be followed by anesthesia. The examination of the blood reveals a polycythemia (due to dehydration) a slight leucopenia and a raised icteric index. The findings in the urine are essentially normal. The conjunctiva is always injected and frequently icteric or grayish, being studded with petechiae and ecchymoses. Motor disturbances in

the innervation centers of the cranial nerves are usually present in more severe cases. Inability to swallow, facial paresis, fibrillar spasms of the muscles of the face and limbs, continuous or periodic grinding of the teeth, rarely amaurosis, râles in the throat and a foul smelling breath and paresis of the lips are characteristic of advanced cases. Such animals may succumb to the infection in from three to eight days or, since the prognosis is hopeless, due to complications such as pneumonia, they are usually destroyed for humane reasons.

Two clinical types are common in the milder cases—the sleepy and the walking type. In the former, the horse may lean with a drooping head against supporting objects in a drowsy somnolent state, occasionally grinding the teeth, or yawning. A peculiar looseness of the lips or a twisting of the upper lip to one side may be noted. The walking type is characterized by circling motions. Such cases may follow close to the fence and only change direction when they come in contact with a turn in the fence or other obstacle.

In approximately 10 to 20 per cent, recovery within a few days is uneventful although the animals may have a nasal discharge for several weeks and exhibit a slightly incoordinated stiff gait and a marked loss in weight. Although the available data are incomplete it has been gradually recognized that many horses fail to regain their original vigor and strength.

GROSS AND MICROSCOPICAL
PATHOLOGY

The anatomical lesions found on autopsy of animals sacrificed before

the onset of complications, are insignificant. Aside from a general icterus of varying degrees of intensity, succulent lymph-nodes and slight parenchymatous changes in the liver and kidneys no gross lesions are found. No enlargement of the spleen has been noted. The spinal fluid may be markedly increased and show a lympho- and leucocytosis (12 to 30 cells per c mm). As a rule the brain and cord are moist and injected irrespective of the advanced dehydration of the tissues which may be present.

Microscopically, the most conspicuous changes consist of hemorrhages around the vessels of the olfactory bulbs and the brain stem, and edema and infiltration of the perivascular sheaths and spaces by mononuclear and polymorphonuclear cells. This cuffing of the veins and arteries is variable in intensity but is always pronounced in the advanced cases of the disease. Scattered patches of infiltration in the gray and white matter are common. It may be very pronounced in the vicinity of the innervation centers of the facial nerves and throughout the entire cord. Areas of infiltration are also noted in the semilunar and peripheral ganglia. However, the distribution and intensity of the inflammatory foci differ from that commonly seen in typical Borna disease. Nuclear inclusions, of the character described as typical of Borna disease by Joest and Degen, have not been observed in the specimens obtained in 1930. However, since Dr. J. A. Howarth has found peculiar intranuclear corpuscles in the ganglion cells of the hippocampus of brains secured from the 1931 epidemic, it is deemed advisable to withhold final con-

clusions as to these until a more detailed search has been completed.

ETIOLOGY

As already mentioned, the disease was originally attributed to the pathogenic action of various organisms or to the toxin of *Cl botulinum*. Through the studies of Meyer, Haring and Howitt⁶ of California, and Record and his associates⁴ of Nevada, evidence has been furnished that the American encephalomyelitis is produced by an ultramicroscopic organism. The virus has been demonstrated in the brain tissues of two of nine horses ill from the spontaneously contracted disease in the 1930 epidemic. It has been passaged through various animals, in particular, guinea pigs. With an improved technique and the selection of the guinea pig as the most susceptible laboratory animal the virus has been recovered in four of eight cases studied during the 1931 outbreak. The failure to demonstrate the infective agent in every case is probably due to the uneven distribution of the virus in the brain tissues and the process of autosterilization which is apparently in progress at the time the disease is clinically recognized. In the course of one transmission experiment only one of eight guinea pigs injected intracerebrally with the brain emulsion of a field case developed symptoms and succumbed to the virus infection. The chances of recovering the virus are greater when the brain stem is tested during the first or second day of the clinical disease than when the material is secured from a horse which has been ill for a longer period.

Blood cultures prepared from 12

horses in various stages of the disease have remained free from readily cultivable micro-organisms. The spinal fluid of four cases sacrificed on the second day of the visible disease remained sterile, while that of 12 horses sacrificed or dead on account of encephalomyelitis gave cultures of hemolytic and nonhemolytic streptococci. These organisms proved to be nonpathogenic to small laboratory animals and horses and are considered as secondary invaders.

Enrichment cultures of pieces of brain and spinal cord in blood broth yielded α and β streptococci in four of ten horses so examined. In every instance the horse which furnished the positive cultures had been ill for some time or had died. The virus was demonstrated in the brain tissues which gave no visible growth on culture media free from living cells.

ANIMALS SUSCEPTIBLE AND MODES OF INFECTION

Guinea pigs, rats, rabbits, mice and monkeys (*Macacus rhesus* and *cynomolgus*) are all susceptible. The young guinea pig, weighing 250 to 300 grams, is probably the most susceptible laboratory animal, the incubation time varies from one to three days after inoculation by the intracerebral route. A sharp febrile reaction, 40° C and above followed within two days by a subnormal temperature, announces the progress of the infection which manifests itself in the form of flabbiness of the abdomen, weakness, salivation, humped cat-pose or inability to rise, tumbling motions, fibrillar tremors of the limbs and paws, loss of weight and death between the fourth and sixth day. Guinea

pigs may be infected by the cerebral, intraperitoneal, subcutaneous and intracutaneous routes. With a potent virus the infection is regularly fatal. Successful infections followed the nasal instillation of virus in the guinea pig and rabbit but not in the horse. Feeding of virulent material to guinea pigs has in the few experiments performed failed to infect. In fact, continuous passage through guinea pigs enhances the virulence for this rodent. During the execution of the experiments, normal guinea pigs have been in intimate contact with infected animals. Thus far no infections by cohabitation have been observed.

Rats are likewise susceptible. The infected animals show general weakness, incoordinated motions and a crusty nasal discharge. Death follows in from six to eight days.

Young rabbits are susceptible to infection by the intracerebral, intraocular, intravenous and nasal routes. The disease is not always fatal. Some rabbits may have fever of short duration, usually from the second to the fourth day after the injection, if chloroformed at this stage the virus may be demonstrated in the brains. In the fatal infections the fever subsides just as in the guinea pig and is followed by general weakness accompanied by vain efforts to rise, abnormal positions and tremors in the extremities are regularly followed by death on the fifth to the tenth day. Passage of the virus through rabbits does not diminish its pathogenicity for guinea pigs, monkeys and horses.

Although mice are apparently less susceptible to infection than rats or guinea pigs they may be infected by

intracerebral or by intraperitoneal routes, provided, in the latter procedure, the central nervous system is injured by an injection of a starch solution. Death on the seventh or eighth day may follow a period of lethargy.

Monkeys are readily infected by the intracerebral route in consecutive passage, with virus obtained directly from horses spontaneously ill of the disease or from experimentally infected rabbits and guinea pigs. The incubation in 18 monkeys has averaged four to six days, and the time between infection and death eight to ten days. Preceding the onset of visible symptoms the body temperature rises above 41°C . Extreme weakness, unsteadiness, somnolence, trembling of the head and extremities, muscle spasms, facial paresis, desire to chew or to gnaw, and a swaying gait to one side may be followed by inability to rise and later by death. The characteristic perivascular and parenchymatous infiltrations are found in the central nervous system. Recovery has been noted in one of the 18 monkeys successfully infected. The virus after passage through the monkey does not lose its virulence for the horse or guinea pig.

Nineteen horses have successfully been infected by the intracerebral and one by the intra-ocular route. Two equine animals contracted the disease following the subcutaneous injection of a total of 12 grams of brain substance from spontaneous cases of encephalomyelitis observed during the month of July, 1931. As a rule, however, repeated inoculations lead to immunity. Since many of the horses have been sacrificed in order to obtain the maximum amount of virus only the early symp-

toms have been carefully studied. The incubation time following intracerebral injection of the virus varies from three to eight days. As a rule the onset of visible signs is preceded by a rise in temperature of from 2° to 3° , varying from 39° to 40.5°C . However, a febrile reaction may not be recorded. Accompanying the fever, slight psychic depression and incoordination in gait may be noted. On the fifth to the tenth day the animal may stagger, grind its teeth, appear dull, somnolent, or aggressive and try to bite. The symptoms of anorexia, defective deglutition and inability to rise become more marked and the animal dies between the sixth and fifteenth day. In general, symptoms and anatomical findings are indistinguishable from those of the spontaneous disease. During 1931 a few horses were found to resist infection by the intracerebral route. The hog and chicken appear to be resistant to infection.

CHARACTERISTICS OF THE VIRUS

The virus passes readily through bacteriological filters such as the Berkfeld V and the Seitz filters. Guinea pigs as well as horses have been successfully infected with such filtrates. In this respect the virus differs from that of Borna disease. There is some evidence that the virus passes through a 30 but not a 35 or 40 per cent collodion ultrafilter. Experiments on guinea pigs indicate that the virus is active in a dilution of 1:1,000 of brain suspension, but not in a dilution of 1:10,000. In the dry state the virulence is retained for at least $5\frac{1}{2}$ months and when kept frozen remains active for five weeks. It is very resistant to glycerin. Held

in neutral 50 per cent glycerin at 41° C the brain tissues secured from an experimentally infected horse remained virulent for 12 months

Miss B Howitt⁵ has shown that the whole blood or the serum from the peripheral circulation and the heart blood of experimentally infected guinea pigs and monkeys collected during the febrile period may contain the virus. In one horse infected by the intracerebral route the virus was demonstrated in the blood with the onset of the febrile reaction (third day after the inoculation). Repeated unsuccessful attempts were made in 1930 and in 1931 to find the virus in the venous blood of horses spontaneously ill from encephalitis. The blood was re-injected subcutaneously into horses or tested on guinea pigs. Experiments to demonstrate the virus in the blood of several experimental horses examined early during the febrile rise of the body temperature were also unsuccessful. The failures may be attributed to the great dilution of the virus in the horse and to the technical procedure which permits only a relatively small amount of blood to be tested on a guinea pig by intracerebral or intraperitoneal injection. As soon as suitable methods of concentration by absorption have been worked out the search for the virus in horses will be resumed. Thus far it has been recovered only from the cerebrum, pons, medulla oblongata, spinal fluid, spinal cord and one lymph node (Records⁴), but not from the liver, spleen and kidneys of the horse. On the other hand Miss B Howitt has found the virus in the peripheral nerves of a monkey and in the salivary glands, spleen, liver and adrenals of guinea pigs, but not in their feces.

IMMUNITY

Veterinarians have reported the recurrence of encephalomyelitis in 16 horses during the 1931 epidemic. A "recurrence probability" of only 0.7 per cent would indicate that relapses are rare and that a clinical attack of the disease is productive of a high degree of immunity. The existence of such a state has been proven in several horses recovered from a spontaneous attack or infections experimentally induced by the intracerebral injection of a very potent virus. Furthermore, in the course of infection-experiments on horses purchased at random during 1931, obviously immune animals have been encountered.

Then again, a comparison of the epidemiological data from 1930 and 1931 makes it perfectly clear that the various waves of encephalomyelitis leave behind a horse population powerfully refractory to subsequent infection.

Accompanying the visible epidemic of 1930 carefully recorded at one ranch (with 687 horses and mules, 67 cases and 32 deaths), a much larger invisible immunizing wave must have established the protection which prevented the occurrence of a single case in 1931. The nature of this immunity in the horse is not known since repeated attempts to demonstrate antibodies capable of neutralizing the virus *in vivo* or *in vitro* in the blood-serum of recovered horses have failed. As an emergency the use of convalescent serum was recommended during the epidemic of 1930 and 1931. Its utter lack of therapeutic value was doubtless due to the absence of protective antibodies in such sera. On the other hand it is im-

portant to note that the sera of rabbits, guinea pigs and monkeys contain specific antiviral substances which, according to Miss B. Howitt, protect laboratory animals. The potency of such sera, in particular those of rabbits, can be increased by repeated subcutaneous injections of virus. These "hyperimmune" sera will protect guinea pigs against a fatal intracerebral or nasal administration of the virus if given one or even four days preceding the infection. These experiments have clearly shown that a therapeutic effect can be expected only during the febrile period when the virus is not as yet fixed in the central nervous tissues. These observations and other theoretical considerations prompted the preparation of "hyperimmune" sera in 17 horses which had either recovered spontaneously or had passed through an unrecognized infection following the intracerebral administrations of small amounts of virus or the subcutaneous injection of large quantities. The immunity of the treated horses was established by one or several intracerebral test injections of the virus. Although the majority of the horses survived these drastic tests only four, upon prolonged immunization furnished sera which neutralized the virus with any degree of certainty *in vitro* and *in vivo*. The pooled serum of these horses has been used intravenously in amounts varying from 500 to 1 000 cc. on 39 horses in various stages of the disease. Thirty animals made a rapid and uneventful recovery, while nine, or 23 per cent (average mortality during 1931, 47 per cent), died or were sacrificed on account of complications. The mortality in a group of 13 horses treated by Dr. F. A. Howarth early in

the course of the disease was two, or 15.3 per cent. An opportunity may be afforded to evaluate more conclusively these encouraging preliminary results in the course of future epidemics.

Experiments having in view the immunization of horses are few. Twelve horses received subcutaneously 60 cc. of a 20 per cent suspension of virulent horse or monkey brain. The injections were well tolerated in 11 animals. One horse after four injections at three day intervals (48 grams of brain material) developed typical symptoms of encephalomyelitis on the fifteenth day after the first, or the fourth day after the last, injection. The horse died on the fifth day of sickness. For several months the immunized horses, which had been tested by intracerebral injections and had been bled repeatedly six to twelve liters, remained well. Subsequently, seven horses sickened with fever, weakness, depression and anorexia, but had no symptoms indicative of localized involvement of the central nervous systems. These animals succumbed to the acute disease or remained weak for months and finally died unexpectedly. At autopsy a splenic tumor and extensive degenerative changes were found in the liver and kidneys. The nature of the disease has not been determined although a malady resembling it clinically and anatomically has been produced in a horse. Efforts made on small laboratory animals by the subcutaneous injection of spleen and liver tissues secured from one of the rapidly fatal cases have failed. It may be mere coincidence but the disease developed only in the horses injected with brain tissue which contained the encephalomyelitis virus. Several equines, which

served as controls, mingled freely in the same pasture and barn with the treated animals. They have remained well.

Further active immunization experiments have been deferred until Miss B Howitt has completed her study on the immunizing properties of the virus treated by various methods.

CROSS IMMUNITY BETWEEN THE VIRUS STRAINS OF 1930 AND 1931 AND BETWEEN OTHER VIRUSES OF THE FILTER-PASSING GROUP

It has been proved by *in vitro* neutralization experiments on small animals that the virus of 1930 is identical with that responsible for the epidemic of 1931. Furthermore, horses immunized with Virus A (1930) prove also refractory to infection by intracerebral inoculation with Virus B (1931).

Monkeys recovered from experimental poliomyelitis are still susceptible to the virus of encephalomyelitis. No cross neutralization exists between the encephalomyelitis serum and the poliomyelitis virus, and *vice versa*, the poliomyelitis serum lacks antiviral substances for the encephalomyelitis virus (Howitt, 1931).⁶

Guinea pigs and rabbits proven immune to the encephalomyelitis virus by repeated intracerebral inoculations may succumb to an injection by the same route of the virus of Borna disease (obtained through the courtesy of Prof W. Zwick). Reverse cross immunity tests have not furnished conclusive results. Although rabbits and guinea pigs may be immunized against the virus of Borna disease, many months may elapse (on account of the characteristically long incubation time) before the existence of an immunity is

definitely established. As already stated, older guinea pigs, and especially older rabbits, possess a natural immunity to the encephalomyelitis. The apparent refractory state to the encephalomyelitis virus of an older animal, which may be immune to Borna disease, may therefore be merely the expression of a natural immunity and in no way prove the existence of cross protection.

TRANSMISSION OF EQUINE ENCEPHALOMYELITIS TO MAN

Although many important questions concerning the nature of the virus, its pathogenesis and portal of entry into the body of the horse, its epidemic spread, etc., remain unsolved, it appears important to continue the investigations, particularly in view of the recently recognized possibility that man may become the victim of the equine encephalomyelitis virus. Conclusive proof is missing, since the brain tissues of the suspected cases were not tested for the presence of a virus. However, the circumstances, and the clinical and anatomical manifestations are sufficiently suggestive to warrant brief consideration.

Case I. On July 23, 1931, the Woodland Clinic admitted C. G., an American ranch hand, age 43, in a semi-comatose condition, and with a history of fever of four days duration, slight headache in the occipital region, and pain in the neck, thorax and lumbar region. He was restless and disoriented. A week preceding the onset he had attended several horses which had become sick and died from encephalomyelitis.

On the day of admission six days after the onset, the patient complained of dryness and headache. He was easily aroused from his semi-comatose state but immediately went to sleep again in no apparent distress. The deep reflexes were sluggish, the Babinski reflex negative, the pupils reacted to light and were normal in size. Borna disease virus

patient became more lethargic. Following a transfusion on July 25, he improved considerably, but succumbed to respiratory failure on July 27, four days after admission. The autopsy revealed no gross anatomical lesions aside from a terminal bronchopneumonia, a moist, markedly injected central nervous system, and a spinal fluid with 200 cells per c.c. (60 per cent polynuclears). An incomplete neuropathological examination demonstrated a slight inflammatory reaction in the meninges, particularly in the depths of the sulci and surrounding the cortical vessels. Focal and diffuse parenchymatous infiltrations with lymphocytes and leucocytes were quite numerous in the cortex, the thalamus and the pons. Dr. G. Y. Rusk, who saw the sections, considers the lesions characteristic of an unusual type of encephalitis resembling the infective encephalitis of the horse.

Case II. In October, through the courtesy of Dr. J. M. Wolfsohn of San Francisco and Dr. Frank W. Lee of Sacramento, a report of a case of encephalitis had been received. The patient in question had cared for his horse which suffered from encephalomyelitis late in September. The course of the patient's illness had all the characteristics of an atypical encephalitis which suggested a suspicious connection with that of the horse. During convalescence a sample of the blood

serum was subjected to an *in vitro* neutralization test with equine encephalomyelitis virus with a negative result. Early in January the patient had not entirely recovered.

In view of these observations* a plea is made that the brain and cord of every fatal atypical human case of encephalitis be examined for the presence of the equine virus (by intracerebral inoculation of guinea pigs or monkeys). The latter species is preferred, since larger amounts of the brain suspension may be injected and the course of the disease may be more readily followed by the inexperienced.

In order to keep a record of the many diversified observations, a series of moving pictures has been taken in the field and in the laboratory, during the epidemics of 1930 and 1931. The film supplements the preceding remarks and thus completes a brief survey of the present knowledge of the North American encephalomyelitis of the horse and mule.

*A third case of non-fatal encephalitis contracted through the handling of infected horses was seen in a veterinarian in July, 1932.

Sensitization to Fungi

By GRAFTON TYLER BROWN, B S , M D , F A C P , *Washington, D C*

MICRO-ORGANISMS may be divided into four distinct groups, namely, the Schizomycetes or bacteria, the Hyphomycetes or molds, the Blastomycetes or yeasts, and the protozoa. The bacteria, molds, and yeasts belong to the plant kingdom, whereas the protozoa belong to the animal kingdom. Fungi, in addition to molds and yeasts, include rusts, smuts, mushrooms, etc. The molds have been classified into five families, with several hundred genera, and thousands of different species. From the viewpoint of allergy, this is a vast unexplored field, and I have selected for study those varieties which have already been reported by other investigators, and also all the different fungi (molds and yeasts) that could be cultured from patients' skin lesions, sputum and nasal secretions, stools, and environmental dusts (house and mattress).

REVIEW OF LITERATURE

Storm van Leeuwen¹ has a clear claim to priority in the field of asthma due to fungi, as he was the first to call attention to the importance of mold allergens in the causation of this disease.

Presented in part before the Georgetown Clinical Society, November 17, 1931 and The Medical Society of the District of Columbia, December 9, 1931. Received for publication, February 1, 1932.

He² attributed the climatic type of asthma so prevalent in Holland, to products of the growth of molds, yeasts, or bacteria, which he termed "climate allergens or miasms." Storm van Leeuwen³ usually worked with six different molds, namely, *Aspergillus flavus*, *Aspergillus fumigatus*, *Aspergillus nidulans*, *Aspergillus niger*, *Mucor*, and *Penicillium*, and by testing his asthmatics intracutaneously with extracts of these molds, found about 50 per cent of them sensitive to mold allergens.⁴ He also found about 20 per cent of his asthma patients sensitive to an allergen formed in grain infected with common mites.

Cadham⁵ reported three examples of asthma due to sensitization to grain rusts.

Hansen,⁶ in Germany, found that 15 per cent of his asthmatic patients gave positive skin reactions to one or more of the following molds: *Aspergillus fumigatus*, *Aspergillus niger*, *Penicillium glaucum*, *Aspergillus glaucus*, and *Aspergillus nidulans*. He was able to reproduce asthmatic attacks in a number of these patients with spores of the reacting molds.

Hopkins, Benham, and Kesten⁷ were the first in the United States to report a case of asthma due to a fungus (*Alternaria*). The patient in addition to being markedly sensitive to *Alternaria*

gave definitely positive skin reactions to several other molds, including *Aspergillus nidulans* cultured from an eczematous lesion on his leg. In this connection it may be stated that some years previously, Niethe,⁸ and Hilgermann⁹ had attributed certain cases of eczema to sensitization to common saprophytic molds which grew on the skin lesions.

Bernton¹⁰ has given an account of one patient with asthma due to a mold—*Aspergillus fumigatus*. Specific treatment was attempted in this case, but was discontinued after the third subcutaneous injection of a 1:5000 extract of *Aspergillus fumigatus*, because of the severe asthma produced by these injections.

Ramirez and Eller¹¹ reported two cases of "contact dermatitis" (dermatitis venenata), and one case of asthma and urticaria, due to sensitization to green *Penicillium*.

Flood¹² has just reported the case of one patient with asthma due to sensitivity to *Mucor plumbeus*. He also states that in a group of 55 patients with chronic asthma, 14 per cent gave positive skin reactions to common dust fungi.

Medical literature contains numerous references to Trichophytin hypersensitivity in persons with deep-seated ringworm infections, and Low,¹³ and Bloch¹⁴ have reviewed the subject in detail. More recently, Jadassohn and Peck¹⁵ showed that this skin hypersensitivity to Trichophytin is also quite constantly present in superficial tinea infections. Sulzberger and Lewis,¹⁶ by means of contact or patch tests with Trichophytin demonstrated that products of fungi are capable of causing an eczematous eruption on a hypersen-

sitive skin. Ramirez¹⁷ has reported a case of hay-fever and asthma which could be traced to Trichophytin sensitization. Sulzberger and Kerr¹⁸ recorded the case of a man with tinea of the hands and feet, who gave immediate, marked, urticarial-wheel reactions to intradermal Trichophytin tests. With this patient's blood serum, they were able to passively transfer the urticarial Trichophytin hypersensitivity to the skin of normal nonsensitive individuals, thus demonstrating the presence in the blood of Prausnitz-Kustner antibodies or specific reagins. Wise and Sulzberger¹⁹ reported the case of a patient with dermatitis, and occasional attacks of urticaria, asthma, and hay-fever, in whom an intradermal test with Trichophytin produced an acute attack of hay-fever and generalized hives, necessitating the administration of epinephrin for relief.

ACKNOWLEDGEMENTS

The numerous fungi used in my work have been obtained from various sources. Quite a number of mold cultures have been sent to me from the Laboratory for Medical Mycology of Columbia University College of Physicians and Surgeons, New York, through the courtesy of Drs. Hopkins and Kesten of the Department of Dermatology, and Dr. Chester W. Emmons, Associate in Mycology. Some of the mold preparations were furnished by Dr. Charles Thom, Principal Mycologist of the U. S. Department of Agriculture. Dr. Storm van Leeuwen of Holland, kindly sent me extracts of six different molds, and also an extract of grain infected with mites. Cultures of a few molds were contributed by Dr. Oscar B. Hunter, Professor of Bacteriology and Pathology at the George Washington University School of Medicine. Dr. Hunter has also rendered me invaluable assistance in carrying on most of the laboratory work referred to in this article, and I gratefully acknowledge his wholehearted cooperation. Dried preparations of

several different strains of yeast were supplied by Standard Brands Incorporated. Mushroom and yeast diagnostic proteins were purchased from the Arlington Chemical Company. Trichophytin (Farbenindustrie) was procured through Metz and Company. Dr. Fred Cadham sent me some uredospores of *Puccinia graminis* (wheat rust).

CULTURE, ISOLATION, AND IDENTIFICATION OF FUNGI

Dusts from various sources, principally house and mattress dusts, were cultured on Czapek's solution agar, dextrose agar, and Sabouraud's medium in pour plates. The plates were then incubated at 37.5° C and at room temperature for from three to seven days. These plates were observed daily during this time for evidence of growth, and the characteristics of all colonies were studied. Daily observations were absolutely essential, because of the profuse growth which sometimes occurs in a relatively short time, making it difficult, if not impossible, to isolate the various molds, yeasts, and bacteria in pure culture, unless subcultures and subsequent plates are made.

As soon as the individual colonies made their appearance, they were fished and subcultured on slants of Czapek's solution agar, 1 per cent dextrose agar, Sabouraud's medium, or such other media as were indicated by the morphology of the colony and the characteristics of the organism. These subcultures were then incubated at 37.5° C and at room temperature until the typical colored hyphae developed, during which time daily observations were made as to the progress and characteristics of the growth. Complete coloration of the aerial hyphae usually developed in from one to seven days, de-

pending to some extent on the character and type of the mold. During this time microscopic preparations were examined, and notations made of the method of development of the stalk, conidiophores, spores, etc., of the molds.

After coloration was complete, final observations were made, macroscopically and microscopically, and in many instances, special fermentation tests and biologic determinations were also made. These findings, together with previous observations, were compared with known mold cultures. These observations and comparisons, together with reference to the works of Buchanan,²⁰ Thom,²¹ and Gulthermond and Tanner,²² were sufficient in most instances to identify the mold or yeast in question, but in other instances it was possible to report the mold or yeast only as belonging to a group, and not as a specific entity. Some of the media used, and their ingredients, are as follows:

CZAPEK'S SOLUTION AGAR

Distilled water	1000.0 cc
Sodium nitrate	3.0 Gm
Potassium phosphate (K_2HPO_4)	1.0 Gm
Magnesium sulphate	0.5 Gm
Potassium chloride	0.5 Gm
Ferrous sulphate	0.01 Gm
Sucrose	30.0 Gm
Agar-agar	15.0 Gm

DEXTROSE AGAR (1 PER CENT)

Distilled water	1000 cc
Sodium chloride	5 Gm
Meat extract	5 Gm
Peptone	10 Gm
Dextrose	10 Gm
Agar-agar	15 Gm

SABOURAUD'S MEDIUM

Distilled water	1000 cc
Peptone	10 Gm
Maltose	50 Gm
Agar-agar	15 Gm

MALTOSE BROTH (2 PER CENT)

Distilled water	1000 c c
Peptone	10 Gm
Sodium chloride	5 Gm
Meat extract	5 Gm
Maltose	20 Gm

The above media are especially suitable for the growth of molds and yeasts. In addition to these, other special media peculiarly adaptable to certain types of growth were used, and, of course, the routine media for the growth and differentiation of the various bacteria were also used in the work of cultivation, isolation, and identification.

PREPARATION OF POWDERS AND
FILTRATES FROM MOLDS

The molds from which powders and filtrates were to be made were inoculated into malt extract broth. These cultures were allowed to stand at room temperature for from 25 to 30 days, during which time a definite and specific felt developed on the surface of the medium. After growing for this length of time, the felt and broth mixture was filtered through sterile filter paper, and the broth filtrate was caught in a sterile container. The felt, which remained on the filter paper, was dried in the incubator for 48 hours. It was then transferred to a sterile mortar and ground into a fine powder. This powder was placed in a sterile tube, and labeled. In some instances, when the felt did not dry after a period of 48 hours in the incubator, it was necessary to freeze it with "dry ice" and grind the felt in this condition, after which, drying was more or less successful.

The broth filtrate was again filtered,

this time through the Berkefeld candle. This filtrate was then transferred to a sterile vaccine vial, and cultured for sterility, both aerobically and anaerobically, for at least 72 hours, after which it was kept in the refrigerator until needed.

The medium used for growing molds for this purpose consists of a 10 per cent solution of malt extract in distilled water. This medium seems to be superior to other preparations, for the development of a massive felt and a potent filtrate. The yeasts were cultured in a manner similar to that used for molds and for bacteria. The types of media most suitable for the growth of yeasts, are sugar broths and beer wort, with or without the addition of agar or gelatin.

METHOD OF PREPARING MOLD
EXTRACTS

Concentrated (2 per cent) glycerin extracts of the various fungi have been prepared, in addition to the dried powdered felts, and sterile broth filtrates just referred to. These glycerin extracts were prepared by adding one gram of the dried powdered felt to 50 c c of an extracting fluid, which consists of 50 per cent glycerin and 50 per cent buffered salt solution. Some sterile glass beads were added to facilitate shaking, and prevent clumping. The buffered salt solution was made by adding 27 grams of sodium bicarbonate and 5 grams of sodium chloride to 1000 c c of distilled water. These extracts were kept in the refrigerator for a week, and thoroughly shaken at least once daily. The extracts were then filtered through a Berkefeld candle and examined for sterility.

FUNGI STUDIED

My collection of fungi at the present time is as follows

Alternaria humicola
Alternaria mali
Alternaria sp (five strains)
Aspergillus candidus
Aspergillus clavatus
Aspergillus conicus
Aspergillus flavipes
Aspergillus flavus
Aspergillus fumigatus (nine strains)
Aspergillus glaucus (eleven strains)
Aspergillus hortai
Aspergillus nidulans (eight strains)
Aspergillus niger (seven strains)
Aspergillus ochraceus
Aspergillus oryzae
Aspergillus parasiticus
Aspergillus terreus
Aspergillus versicolor (two strains)
Aspergillus Wentii
Aspergillus sp
Cephalothecium roseum (*Trichothecium roseum*)
Citromyces sp
Cladosporium sp
Dicoccum asperum
Endothia parasitica
Fusarium orthoceras
 Grain smut
Hormodendrum hordei
Monilia albicans (two strains)
Monilia parapsilosis
Monilia sitophila
Monilia sp
Mucor circinelloides
Mucor ercetus
Mucor fragilis
Mucor griseocyanus
Mucor mirus
Mucor mucedo (eight strains)
Mucor piriformis
Mucor plumbeus (three strains)
Mucor racemosus (two strains)
Mucor sp (three strains)
 Mushroom (food)
Neurospora sitophila (ascomycetous stage of *Monilia sitophila*)
Paccilomyces varioti

Penicillium brevicaulis
Penicillium chlorophaeum
Penicillium chrysogenum
Penicillium cyclopium
Penicillium elongatum
Penicillium expansum (seven strains)
Penicillium glaucum (green—nine strains)
Penicillium griseo-roseum
Penicillium italicum (two strains)
Penicillium lanosum
Penicillium oxalicum
Penicillium Pfefferianum
Penicillium sp (two strains)
Polyporus versicolor
Puccinia graminis (uredosporces)
Rhizopus nigricans
Saccharomyces cerevisiae (four strains)
Saccharomyces torulac
Saccharomyces sp (three strains)
Sporotrichum Beurmanni
Trichoderma Konigii
Trichophyton gypsum
Trichophyton mixed (gypsum, cerebriforme, migroides, crateriforme, rosaceum, and violaceum)
Ustilago maydis (corn smut)

• TESTING AND TREATING WITH FUNGI

A considerable number of patients with asthma, eczema, hay-fever and other related conditions, have been tested more or less routinely for sensitization to fungi. The cutaneous or "scratch" method has been used almost exclusively, but in a few selected cases resort has been had also to the intradermal method of testing.

The crude molds growing on Sabouraud's or Czapek's media may be used for cutaneous testing, but they are somewhat awkward and messy to handle. The principal objection, however to the use of crude molds for diagnostic skin tests is that the spores get in the air and contaminate almost every-

thing in the office or clinic where they are being handled

The dried powdered felt makes satisfactory material for the "scratch" test, and is dissolved on the skin with tenth-normal sodium hydroxide solution, just as in tests with other dried protein preparations. The same objection, however, applies to the use of the dried felt for test purposes as to the crude molds, namely, that some of the spores are bound to get into the air, and, if viable, will contaminate almost anything they come in contact with.

The sterile broth filtrates may be used undiluted for cutaneous or intradermal testing, and in proper dilution for treatment purposes. However, as these filtrates consist of nutrient broth without any preservative, they are quite easily contaminated, and must, therefore, be handled with strict aseptic precautions. Sterile normal salt solution was used to prepare 1:10, 1:100, and 1:1,000 dilutions of the broth filtrates for treatment purposes.

The concentrated glycerin extracts previously referred to are potent and stable, and perfectly satisfactory for cutaneous testing, but because of the high content of glycerin, must be diluted at least ten times with sterile buffered salt solution to make them suitable for intradermal testing. In preparing dilutions of the glycerin extracts for treatment purposes, however, the glycco-saline extracting fluid should be used as diluent, to maintain the potency and sterility of these dilutions.

In testing with the various preparations of the fungi, suitable controls should be used, namely, tenth-normal sodium hydroxide for the crude molds and the dried powders, sterile malt ex-

tract broth for the broth filtrates, the glycco-saline extracting fluid for the glycerin extracts, and phenolized salt solution for the *Trichophyton*.

CASE REPORTS

Excerpts from case records of some of my patients will now be given, to illustrate certain phases of the subject under discussion.

Case I Mr. T, aged 37, with chronic asthma, had noticed that his trouble was aggravated by damp, musty places, and rainy weather. The asthma was so constant that it necessitated his taking one or two $\frac{3}{8}$ grain ephedrine capsules from three to six times daily to keep it under control.

Exhaustive skin testing by the cutaneous or "scratch" method showed him to be definitely sensitive to a great many different kinds of molds. In the order of their importance according to the size of the skin reaction, they were *Penicillium glaucum*, *Penicillium mixed*, *Aspergillus nidulans*, *Aspergillus parasiticus*, *Mucor mixed*, *Alternaria mali*, *Aspergillus fumigatus*, *Aspergillus terreus*, *Penicillium cyclopium*, *Aspergillus glaucus*, *Penicillium expansum*, *Penicillium italicum*, *Aspergillus niger*, *Penicillium lanosum*, *Aspergillus oryzae*, *Citromyces sp.*, *Penicillium chlorophanum*, *Mucor mucedo*, and *Aspergillus candidus*. Some of these will be recognized as newcomers to be added to the already lengthy list of allergens.

With this patient's blood serum, a single attempt was made to transfer the sensitization to *Penicillium mixed*, *Aspergillus nidulans*, and *Aspergillus parasiticus* to the skin of a normal nonsensitive person. The *Penicillium* mixture gave a positive transfer, but the *Aspergilli* were negative.

Mr. T's dominant reaction was to the dried felt from a flask which had been inoculated with two green *Penicillia* (*P. chlorophanum* and *P. chrysogenum*), and consisted of an irregular urticarial wheal $1\frac{1}{2}$ inches in diameter, surrounded by a zone of erythema, and accompanied by a subjective sensation of itching. The sterile broth filtrate from this

same flask also gave a marked positive reaction. Strange as it may seem, tests with dried felt and broth filtrate from the same culture of *P. chlorophaeum*, and with felt and filtrate from the culture of *P. chrysogenum*, were entirely negative. Retests with subcultures of these two molds were also negative, with the exception of a mild positive reaction to *P. chlorophaeum*. It would seem that these two green *Penicillia* growing together produced some allergenic substance that was not formed by either mold growing alone. Another possible explanation would be that the original flask containing the mixture of the two *Penicillia* had become contaminated with some other mold to which this particular person happened to be highly sensitive. This is quite unlikely, however, when we consider that this patient was carefully tested with my entire collection of mold preparations, without showing any reaction to equal even the one elicited by the dried felt from the green *Penicillium* mixture. Similarly, this individual gave a marked positive reaction to a skin test with the dried felt from a flask which had been inoculated with four different *Penicillia* (*P. elongatum*, two strains of *P. eriposum*, and *P. cyclopium*), but tests with preparations of each of these same four *Penicillia* separately, were all completely negative with the exception of a moderate reaction to the dried felt of *P. cyclopium*. Furthermore, this same person gave a definitely positive reaction to the dried felt from a flask which had been inoculated with five different *Mucors* (*M. plumbeus*, *M. griseocyanus*, *M. circinelloides*, *M. mirus*, and *M. mucedo*), but failed to react to preparations of any of these same five *mucors* separately, with the exception of a slight reaction to the dried felt of *M. mucedo*.

These three instances bring up, for the first time, the question of symbiosis in sensitization to fungi. In an effort to further elucidate this problem of symbiotic allergens, three additional flasks have been inoculated respectively with subcultures of the two green *Penicillia*, the four *Penicillia*, and the five *Mucors* just referred to, for the preparation of dried felts and broth filtrates. When these are ready, they will be tested on this same patient to see if they will react similar-

ly to the preparations from the original mixtures.

It is interesting to note that this patient's asthma was definitely aggravated by inhalation of some of the spores, incident to skin testing him with the crude molds and the dried felt preparations. After this happened several times, the precaution was taken of tying a folded handkerchief over his nose and mouth while the dry mold preparations were being handled in his presence.

Cutaneous tests with crude nonsterile extracts of his own house dust, mattress dust, pillow dust, bedroom rug dust, and automobile upholstery dust were all negative. These individual dust specimens were collected with a vacuum cleaner, with paper sacks substituted for the cloth bag of the cleaner, as described by Cohen.²³ In spite of his not reacting to these autogenous dust extracts, it was deemed advisable for him to purchase a new mattress and pillows and have them covered with Dupont's satin fabrikoid, which is impervious to dust and molds. Also, his sleeping quarters were thoroughly cleaned and all unnecessary dust catchers were eliminated. Following these changes, he has been able to discontinue the ephedrine entirely, and although he still has some asthma every day, the attacks now are relatively mild and of short duration. It would be impossible to say how much of this improvement should be attributed to the changes in his sleeping quarters, for he was being given at the same time, an intensive series of injections of concentrated peptone extract, for its nonspecific desensitizing effect. Unless the asthma leaves him entirely in the near future, he will be given a course of hyposensitizing injections with various dilutions of the broth filtrate from the green *Penicillium* mixture previously referred to.

Case II Mr. C. aged 32 was referred to me with severe asthma of eleven years' duration. He had noticed that while staying in certain places he was practically free of asthma for months at a time. His asthma was definitely worse in summer, and better in cold, dry weather. The attacks, which were accompanied by a good deal of coughing, almost always came on indoors and usually occurred either at night or in the fore-

retiring, or early in the morning. He also stated that dust affected him. These points in his history suggested sensitization to molds.

Skin testing by the cutaneous method showed him to be definitely sensitive to extracts of his own mattress and house dusts, the former being slightly more potent than the latter. He also gave definitely positive reactions to "scratch" tests with the dry dusts themselves. That these dust reactions were due to a specific sensitization, and not merely to a nonspecific irritation or histamine reaction, was proven by the fact that these same dusts failed to react when they were tested on the skin of other persons (allergic and nonallergic). Skin tests with epidermals, pollen, orris root, and other air-borne substances failed to show a reaction that would in any way account for the allergenic properties of his house and mattress dusts. His mattress was cotton felt but a test with cottonseed protein was completely negative. Furthermore, "scratch" tests with dust extracts from various other sources, were all negative. It seemed, therefore, that his specific dust sensitization must be due to some fungus which was present in his mattress, and also to a slightly lesser degree in his house dust. However, "scratch" tests with a number of stock mold preparations were completely negative.

When he was tested intradermally with sterile broth filtrates and extracts of various molds, positive reactions were obtained to the following in the order named: *Aspergillus nidulans*, *Aspergillus fumigatus*, *Aspergillus niger*, *Penicillium* mixed (*P. elongatum*, *P. expansum*, and *P. cyclopium*), *Mucor plumbeus*, *Paecilomyces varioti*, and *Cephalothecium roseum*. Some of these reactions were immediate and some delayed. However, as it was necessary to inject these mold preparations intradermally to obtain positive reactions, none of them definitely explained his immediate urticarial reactions to "scratch" tests with his own house and mattress dusts.

His house dust was then cultured, and showed the following: *Aspergillus niger*, *Aspergillus fumigatus*, *Citromyces* sp., *Saccharomyces* sp., *Bacillus megatherium*

(group), *Bacillus subtilis*, *Bacillus mycoides*, *Bacillus roseus*, and a gram-positive coccus. These were isolated in pure culture and tested by the "scratch" method, but none of them reacted.

In view of the possibility that the reactivity of the house dust might be due to some symbiotic allergen, a flask was inoculated with all of the fungi and bacteria cultured from his house dust, and dried felt and sterile broth filtrate were prepared from this mixture. He will be tested with these preparations during his next visit.

Cultures from his sputum showed *Aspergillus fumigatus*, *Streptococcus hemolyticus*, *Streptococcus viridans*, and *Staphylococcus aureus*. His mattress dust was then cultured with the following findings: *Penicillium glaucum*, *Aspergillus glaucus*, *Citromyces* sp., *Penicillium expansum*, *Aspergillus niger*, *Mucor mucedo*, *Staphylococcus citreus*, *Bacillus megatherium* (group), *Bacillus mesentericus*, and *Bacillus* (chromogenic) *flavus*. It will be noted that four out of the six kinds of molds isolated from the mattress dust were different from those found in his house dust. As I have as yet had no opportunity to test him with these molds from his mattress dust, it is perfectly possible that one of them may be the positive reactor. The reacting substance in the dust is not likely to be any of the bacteria found, as bacteria very rarely give immediate skin reactions. I can recall only two instances of immediate urticarial reactions to "scratch" tests with bacterial proteins.

This patient was told to have his home thoroughly cleaned, and then kept as free of dust as possible. He was also advised to purchase a new mattress and pillows, and have them covered with rubber sheeting to make them impervious to dust. Since he has been sleeping on the new mattress, his asthma has been definitely better. It is significant to note that recently when he tried sleeping on an old cot, his asthma was as bad as ever. When he returned to his new bed, the asthma promptly improved again.

Case III Mr G, aged 51, was referred to me with asthma of about sixteen years' standing, which had started with coughing at night. At times he was also troubled in

the morning with hay-fever symptoms, consisting of burning and watering of the eyes, and sneezing, which symptoms were frequently followed by asthma. His asthma was always worse in the summer and fall and he had lost considerable time from work because of severe attacks at that time of the year. He stated that dust affected him and made him sneeze.

Cutaneous tests with pollens, animal epidermals, bacteria, foods, etc., failed to reveal the cause of his asthma. However, "scratch" tests with extracts of his own mattress and bedroom rug dusts gave definite positive reactions. He also reacted in the same way to an extract of dust from the mattress of another patient living in a different section of the country. Mr. G's mattress was cotton felt and the bedroom rug was woolen, but he was completely negative to tests with cottonseed, cotton, and wool proteins. Tests at that time with some of the more important stock mold preparations were completely negative, with the exception of slight or doubtful reactions to *Cephalothecium roseum*, *Penicillium expansum*, and *Penicillium elongatum*.

He was advised to get rid of the musty old rug which had been on his bedroom floor for over fifteen years, and also to vacuum, sun, and air his mattress at frequent intervals. Since the removal of this rug over a year ago, he has been entirely free of asthma.

Cultures of his mattress dust showed *Penicillium chrysogenum*, *Altaria sp.*, *Aspergillus glaucus*, *Aspergillus niger*, *Mucor mucedo*, *Bacillus subtilis*, *Bacillus megatherium* black (subtilis group), *Bacillus megatherium*—brown (subtilis group), *Bacillus mesentericus* (*fuscus panis viscosi*), *Bacillus roseus*, and a gram-negative bacillus. He has never given me the opportunity to test him with these molds isolated from his dust, and *Penicillium chrysogenum*, *Aspergillus glaucus*, and *Mucor mucedo* were not included in his original tests with stock molds, so one of these three varieties of molds could readily be the allergenic offender. I am most suspicious of the *Penicillium*, for the green *Penicillia* are more frequent reactors than either *Aspergillus alancus* or *Mucor mucedo*.

Case IV Mrs. T, aged 68, was referred to me with asthma of about eighteen years' duration. She stated that dust of any kind affected her.

Skin tests by the "scratch" method, including the most important molds, were all negative. Cultures from her sputum, in addition to the common respiratory micro-organisms, showed *Alternaria sp.* This finding has probably no significance in her case, however, as she gave absolutely no reaction to a "scratch" test with this particular strain of *Alternaria*, and furthermore, intradermal tests with stock *Alternaria* filtrates were completely negative. When tested intradermally with other important molds, however, this patient gave positive delayed reactions to the following: *Aspergillus nidulans*, *Penicillium mixed*, *Aspergillus conicus*, *Paccilomyces varioti*, *Mucor mixed*, and *Cephalothecium roseum*.

Case V Miss S, 14 years of age, was brought to me with bad eczema which she had had ever since she was a baby in arms. The eczema was practically limited to the exposed parts of her body, namely, her face, neck, and arms. Although this trouble was present throughout the year, it was worse in hot weather. She stated that house dust made her sneeze, and irritated her skin. The eczema left her whenever she went to the mountains, but came back promptly upon her return to sea-level.

Cutaneous tests with fungi showed positive reactions to *Saccharomyces cerevisiae* and *Aspergillus fumigatus*, and slight or doubtful reactions to *Monilia mixed*, *Penicillium expansum*, *Aspergillus terreus*, *Trichophyton gypsum*, *Trichophyton mixed*, *Aspergillus nidulans*, *Citromyces sp.*, and *Penicillium griseo-roseum*.

Skin tests with crude extracts of her own general house dust, bedroom rug dust, mattress dust and pillow dust were all negative. Cultures from her skin lesions failed to reveal any fungi.

As she gave a definite positive skin reaction to the protein of yeast (*Saccharomyces cerevisiae*) she was advised to eliminate from her diet all light bread because of its yeast content. Following this change she reported an improvement in the eczema. After doing without bread for some time she was

retiring, or early in the morning. He also stated that dust affected him. These points in his history suggested sensitization to molds.

Skin testing by the cutaneous method showed him to be definitely sensitive to extracts of his own mattress and house dusts, the former being slightly more potent than the latter. He also gave definitely positive reactions to "scratch" tests with the dry dusts themselves. That these dust reactions were due to a specific sensitization, and not merely to a nonspecific irritation or histamine reaction, was proven by the fact that these same dusts failed to react when they were tested on the skin of other persons (allergic and nonallergic). Skin tests with epidermals, pollen, orris root, and other air-borne substances failed to show a reaction that would in any way account for the allergenic properties of his house and mattress dusts. His mattress was cotton felt but a test with cottonseed protein was completely negative. Furthermore, "scratch" tests with dust extracts from various other sources, were all negative. It seemed, therefore, that his specific dust sensitization must be due to some fungus which was present in his mattress, and also to a slightly lesser degree in his house dust. However, "scratch" tests with a number of stock mold preparations were completely negative.

When he was tested intradermally with sterile broth filtrates and extracts of various molds, positive reactions were obtained to the following in the order named: *Aspergillus nidulans*, *Aspergillus fumigatus*, *Aspergillus niger*, *Penicillium* mixed (*P. elongatum*, *P. expansum*, and *P. cyclopium*), *Mucor plumbeus*, *Paecilomyces varioti*, and *Cephalothecium roseum*. Some of these reactions were immediate and some delayed. However, as it was necessary to inject these mold preparations intradermally to obtain positive reactions, none of them definitely explained his immediate urticarial reactions to "scratch" tests with his own house and mattress dusts.

His house dust was then cultured, and showed the following: *Aspergillus niger*, *Aspergillus fumigatus*, *Citromyces* sp., *Saccharomyces* sp., *Bacillus megatherium*

(group), *Bacillus subtilis*, *Bacillus mycoides*, *Bacillus roseus*, and a gram-positive coccus. These were isolated in pure culture and tested by the "scratch" method, but none of them reacted.

In view of the possibility that the reactivity of the house dust might be due to some symbiotic allergen, a flask was inoculated with all of the fungi and bacteria cultured from his house dust, and dried felt and sterile broth filtrate were prepared from this mixture. He will be tested with these preparations during his next visit.

Cultures from his sputum showed *Aspergillus fumigatus*, *Streptococcus hemolyticus*, *Streptococcus viridans*, and *Staphylococcus aureus*. His mattress dust was then cultured with the following findings: *Penicillium glaucum*, *Aspergillus glaucus*, *Citromyces* sp., *Penicillium expansum*, *Aspergillus niger*, *Mucor mucedo*, *Staphylococcus citreus*, *Bacillus megatherium* (group), *Bacillus mesentericus*, and *Bacillus* (chromogenic) *flavus*. It will be noted that four out of the six kinds of molds isolated from the mattress dust were different from those found in his house dust. As I have as yet had no opportunity to test him with these molds from his mattress dust, it is perfectly possible that one of them may be the positive reactor. The reacting substance in the dust is not likely to be any of the bacteria found, as bacteria very rarely give immediate skin reactions. I can recall only two instances of immediate urticarial reactions to "scratch" tests with bacterial proteins.

This patient was told to have his home thoroughly cleaned, and then kept as free of dust as possible. He was also advised to purchase a new mattress and pillows, and have them covered with rubber sheeting to make them impervious to dust. Since he has been sleeping on the new mattress, his asthma has been definitely better. It is significant to note that recently when he tried sleeping on an old cot, his asthma was as bad as ever. When he returned to his new bed, the asthma promptly improved again.

Case III Mr. G., aged 54, was referred to me with asthma of about sixteen years' standing, which had started with coughing at night. At times he was also troubled in

the morning with hay-fever symptoms, consisting of burning and watering of the eyes, and sneezing, which symptoms were frequently followed by asthma. His asthma was always worse in the summer and fall and he had lost considerable time from work because of severe attacks at that time of the year. He stated that dust affected him and made him sneeze.

Cutaneous tests with pollens, animal epidermals, bacteria, foods, etc., failed to reveal the cause of his asthma. However, "scratch" tests with extracts of his own mattress and bedroom rug dusts gave definite positive reactions. He also reacted in the same way to an extract of dust from the mattress of another patient living in a different section of the country. Mr. G's mattress was cotton felt and the bedroom rug was woolen, but he was completely negative to tests with cottonseed, cotton, and wool proteins. Tests at that time with some of the more important stock mold preparations were completely negative, with the exception of slight or doubtful reactions to *Cephalothecium roseum*, *Penicillium expansum*, and *Penicillium elongatum*.

He was advised to get rid of the musty old rug which had been on his bedroom floor for over fifteen years, and also to vacuum, sun, and air his mattress at frequent intervals. Since the removal of this rug over a year ago, he has been entirely free of asthma.

Cultures of his mattress dust showed *Penicillium chrysogenum*, *Alternaria* sp., *Aspergillus glaucus*, *Aspergillus niger*, *Mucor mucedo*, *Bacillus subtilis*, *Bacillus megatherium* black (subtilis group), *Bacillus megatherium*—brown (subtilis group), *Bacillus mesentericus* (*fuscus panis viscosi*), *Bacillus roseus*, and a gram-negative bacillus. He has never given me the opportunity to test him with these molds isolated from his dust, and *Penicillium chrysogenum*, *Aspergillus glaucus*, and *Mucor mucedo* were not included in his original tests with stock molds, so one of these three varieties of molds could readily be the allergenic offender. I am most suspicious of the *Penicillium* for the green *Penicillium* are more frequent reactors than either *Aspergillus glaucus* or *Mucor mucedo*.

Case IV Mrs. T, aged 68, was referred to me with asthma of about eighteen years' duration. She stated that dust of any kind affected her.

Skin tests by the "scratch" method, including the most important molds, were all negative. Cultures from her sputum, in addition to the common respiratory micro-organisms, showed *Alternaria* sp. This finding has probably no significance in her case, however, as she gave absolutely no reaction to a "scratch" test with this particular strain of *Alternaria*, and furthermore, intradermal tests with stock *Alternaria* filtrates were completely negative. When tested intradermally with other important molds, however, this patient gave positive delayed reactions to the following: *Aspergillus nidulans*, *Penicillium mixed*, *Aspergillus conicus*, *Paccilomyces varioti*, *Mucor mixed*, and *Cephalothecium roseum*.

Case V Miss S, 14 years of age, was brought to me with bad eczema which she had had ever since she was a baby in arms. The eczema was practically limited to the exposed parts of her body, namely, her face, neck, and arms. Although this trouble was present throughout the year, it was worse in hot weather. She stated that house dust made her sneeze, and irritated her skin. The eczema left her whenever she went to the mountains, but came back promptly upon her return to sea-level.

Cutaneous tests with fungi showed positive reactions to *Saccharomyces cerevisiae* and *Aspergillus fumigatus*, and slight or doubtful reactions to *Monilia mixed*, *Penicillium expansum*, *Aspergillus terreus*, *Trichophyton gypsum*, *Trichophyton mixed*, *Aspergillus nidulans*, *Citromyces* sp. and *Penicillium griseo-roseum*.

Skin tests with crude extracts of her own general house dust, bedroom rug dust, mattress dust and pillow dust were all negative. Cultures from her skin lesions failed to reveal any fungi.

As she gave a definite positive skin reaction to the protein of yeast (*Saccharomyces cerevisiae*), she was advised to eliminate from her diet all light bread, yeast cakes, etc., of high content. Following this elimination, she reported an improvement in the eczema. After doing without bread for several days, she

eating it again, which apparently caused an aggravation of her skin trouble

Case VI. Mrs F, aged 67, was referred to me in 1926 with severe asthmatic bronchitis, which she had had almost constantly for about nine or ten years. Cultures from her sputum showed, in addition to the common respiratory organisms, a number of colonies of *Aspergillus fumigatus*. A concentrated saline suspension of the spores of this mold was prepared, and tested intradermally on this patient, but with negative results. The failure to obtain a positive reaction may have been due to the fact that heat was used to sterilize the spore suspension, which could have destroyed its allergic reactivity.

Case VII. Miss J, aged 26, was referred to me complaining of bad sneezing spells, irritation of her throat, and recurrent attacks of rather severe pains in her back, shoulders, and limbs. This trouble was usually worse in the summer.

Thorough skin testing by the "scratch" method revealed a marked positive reaction to *Alternaria mali*, and slight or doubtful reactions to *Alternaria humicola* and cheese. *Alternaria mali* is the cause of apple leaf-spot disease, and this patient lives in Winchester, Va., which is the heart of the apple-growing country. It seems highly probable, therefore, that her symptoms, especially the sneezing and irritation of her throat, have been due to inhalation of the spores of this mold. As to the possibility that the recurring attacks of pain in various parts of her body were due to *Alternaria* sensitization, I should like to call attention to the observation of Gehlen and Otto,²⁴ that many of their patients with asthma also had rheumatic symptoms, and that most of them gave positive reactions to cutaneous tests with mold fungi. After testing 125 such patients, most of whom lived in damp houses, they concluded that there was an etiological relationship between asthma and rheumatism, and that sensitization to mold fungi was of some significance in the pathogenesis of these diseases.

Miss J is showing very definite improvement under gradually increasing doses of *Alternaria mali* filtrate. Careful culturing of a single specimen of this patient's house dust

failed to reveal any *Alternaria*, but showed *Mucor piriformis*, *Aspergillus nidulans*, *Mucor racemosus*, *Aspergillus glaucus*, *Aspergillus fumigatus*, *Penicillium glaucum*, *Bacillus subtilis*, and *Bacterium veirnaformis*. The failure to find *Alternaria* in her house dust, may have been due to the fact that the dust was collected from a newly built house, into which she had just recently moved.

Case VIII. L, a girl, 11 years of age, was referred to me with asthma of five years' duration. Her trouble was worse at night than in the daytime, and was worse indoors than out. She was better at school than at home, and during several visits away from home was entirely free of asthma.

"Scratch" tests showed an immediate urticarial reaction to dust from her own mattress, and a delayed positive reaction to an unidentified yeast from another patient's house dust. L's mattress was cotton felt, but she gave no reaction whatever to tests with cotton and cottonseed. Culture of a specimen of dust from her mattress showed *Mucor plumbeus*, *Aspergillus glaucus*, *Penicillium expansum*, and *Penicillium glaucum*, but tests with these molds were completely negative. Likewise, tests with my stock molds were all negative.

A flask was then inoculated with the four molds isolated from her mattress dust, and dry powdered felt and sterile broth filtrate were prepared from this mixture. No reactions were obtained, however, when she was tested with these symbiotic mold preparations. As it was believed that something must have been missed, another specimen of dust was collected from the same mattress, and then cultured for fungi, with the following findings: *Saccharomyces* sp., *Aspergillus ochraceus*, *Penicillium brevicaulis*, *Alternaria* sp., *Aspergillus flavipes*, and *Aspergillus oryzae*. "Scratch" tests with these six fungi were all negative, with the exception of very slight or doubtful reactions to the *Alternaria* and *Aspergillus oryzae*. In other words, examination of two separate specimens of dust collected from the same mattress, revealed entirely different fungi, none of which explained this patient's sensitivity to the dust. This shows the multiplicity of molds present in dust, and the difficulty in locating the

offending one by the culture method. From the fact that a small quantity of the dry dust from the mattress, when applied to a "scratch" on the patient's skin and moistened with a drop of tenth-normal sodium hydroxide, gave a definite positive reaction, it may be assumed that the reacting substance was generally distributed throughout the dust. If the reacting substance consists of spores of some fungus, which is the most probable explanation, the failure to find this fungus may be due to the spores being non-viable from age and drying, which would not interfere with their allergenic properties, but would prevent their growth when transferred to culture media.

As *Aspergillus ochraceus*, *Penicillium brevicaulis*, *Aspergillus flavipes*, and *Aspergillus oryzae* isolated from the second specimen of mattress dust, were not included in my collection of stock molds, dry powdered felt and sterile broth filtrate were prepared from each, and she will be tested with these preparations on her next visit. Also, two separate flasks were inoculated with all ten of the fungi isolated from both specimens of the mattress dust, and to one of these flasks was added some sterile cotton fiber and cottonseed meal, to reproduce, as nearly as possible, the conditions within the mattress. Dried felt and broth filtrates have been prepared from each of these flasks. As it was thought that the fungi might have produced the allergenic substance by some action on the cottonseed protein within the mattress, a batch of cottonseed meal was moistened with water and inoculated with all ten fungi isolated from the mattress dust. After this mixture had stood for about a month, being remoistened when necessary to promote free growth of the fungi, the mass was dried, and will be used to test this patient.

When it was discovered that she was sensitive to the dust from her own mattress, instructions were given to get rid of this mattress, and substitute another one, the dust from which did not react on her skin. Since getting rid of the offending mattress, about a year ago, she has remained entirely free from asthma.

Case IX Master D, aged 11 years, was brought to me with asthma, with which he

had suffered since he was about one year old. His trouble was worse in the spring and summer. One particularly severe attack followed a night spent in the cabin of a schooner, and although he was perfectly well when he went to bed, he was so bad by the next day that he had to be carried from the boat. I could not get hold of a specimen of dust from the mattress he used on the boat, but in all probability it was full of mold.

Thorough "scratch" testing gave marked positive reactions to *Alternaria mali*, *Saccharomyces sp.*, *Saccharomyces cerevisiae*, and *Monilia sitophila*, and moderate to mild positive reactions to *Dicoccum asperum*, *Aspergillus nidulans*, grain smut, *Penicillium lanosum*, *Monilia mixed*, *Aspergillus fumigatus*, mushroom (food), *Alternaria humicola*, *Aspergillus clavatus*, *Aspergillus conicus*, *Aspergillus terreus*, *Penicillium cyclospium*, and *Penicillium elongatum*. In spite of his multiple sensitivity to fungi, "scratch" tests with various dust extracts, stock and autogenous, were all negative.

He thought that his asthma was aggravated by contact with cats or dogs, but skin tests with the proteins of cat and dog hair were negative. Some of the molds to which he is sensitive could be present on the hair of cats and dogs, and account for his having symptoms from proximity to these animals, similar to the case reported by Hansen.⁶

With this patient's blood serum, a perfect transfer of the *Alternaria mali* sensitization to the skin of a normal nonsensitive person was obtained. A single unsuccessful attempt was made to passively transfer the *Aspergillus nidulans* and mushroom sensitizations.

It was decided to give him specific treatment for the *Alternaria mali* sensitization, and the desensitizing injections were started with 0.1 c.c. of a 1:1,000 dilution of a broth filtrate of this mold. The doses have been gradually increased at weekly intervals, and at the present writing he is getting 0.26 c.c. of a 1:10 dilution of *Alternaria mali* broth filtrate. There have been no constitutional reactions following any of these doses. Since the institution of this treatment he has been practically free of asthma.

Case X Miss G, 54 years old, was referred to me with chronic asthma. Her first

attack came on just after she had been doing her spring housecleaning

"Scratch" tests showed slight reactions to the following molds *Cephalothecium roseum*, *Aspergillus nidulans*, *Cladosporium* sp., grain smut, *Alternaria* mah, *Puccinia graminis*, *Aspergillus horii*, *Trichophyton gypsum*, and *Alternaria* sp. She gave a doubtful reaction to a crude extract of dust from her mattress. The mattress was made of horse hair, but tests with the proteins of horse hair or dander were completely negative. Cultures of dust from this mattress showed *Aspergillus glaucus*, *Mucor mucedo*, *B. coli* group, *Bacillus megatherium* (subtilis group), *Bacillus subtilis*, and *Bacillus mesentericus* (*fuscus pans viscosi*), but skin tests with these cultures were all negative. Two separate flasks were inoculated with all of the molds and bacteria isolated from the mattress dust, and some horse hair was also added to one of these flasks. Slight reactions were obtained when she was tested cutaneously with the dried felt from both of these flasks, the mixture with the added horse hair giving a little larger reaction than the other. She was advised to sleep on another mattress, the dust from which gave absolutely no reaction when she was skin tested with it.

This patient was also tested intradermally with concentrated broth filtrates of a number of my stock molds, and gave definite, delayed positive reactions to the following *Cephalothecium roseum*, *Aspergillus nidulans*, *Mucor mixed*, *Penicillium mixed*, and *Penicillium glaucum*. The reaction to *Cephalothecium roseum* stayed inflamed and itched for a week, and the skin desquamated over this area. The reaction to *Aspergillus nidulans* itched for three days.

It was then decided to give her desensitizing injections with the *Cephalothecium roseum* broth filtrate. Treatment was started with 0.05 c.c. of a 1:10 dilution, and the doses are being gradually increased at weekly intervals. Her asthma is better, although she still has some trouble every day.

Case XI Miss M, 14 years of age, was brought to me with eczema, involving the face, neck, and arms, which had troubled her since she was 3 weeks old. Skin tests by the

"scratch" method gave a marked positive reaction to *Aspergillus fumigatus*, and slight or doubtful reactions to *Monilia sitophila*, *Citromyces* sp., and *Monilia* sp. Cultures of scales from her skin lesions were negative for fungi, but culture of her stool showed *Aspergillus glaucus*. I have not yet had an opportunity to test this patient with the particular strain of *Aspergillus glaucus* isolated from her stool.

Case XII Master J, aged 5 years, was brought to me with bronchitis of fifteen months' duration, and asthma which he had had every day for the preceding nine months. His asthmatic attacks were so severe at times, that his parents were afraid he would die in one of them. His only real relief was obtained when they took him west to a much higher altitude, where he was entirely free of asthma.

Skin tests by the "scratch" method, including a few of the more important stock molds, were all negative, except for a positive reaction to an extract of dust from his mattress, and mild positive reactions to horse serum and autogenous sofa, chair, and pillow dust extracts. With reference to the reaction to horse serum, I might state that he had been given diphtheria toxin-antitoxin just prior to the onset of his bronchitis.

They were advised to vacuum, sun, and air his mattress at frequent intervals. The sofa and overstuffed chair were removed from his bedroom, and his pillow was changed. His mother then took him west again for the summer, and since their return some months ago, he has had only one attack of asthma.

Case XIII. Master R, 13 years of age, was brought to me with bad asthma which he had had since he was a tiny baby. He stated that any kind of dust "choked him up."

On cutaneous tests, he gave a mild positive reaction to a crude extract of his own house dust, and a definite positive reaction to short ragweed pollen. Cultures of his house dust showed *Mucor fragilis*, *Mucor erectus*, *Penicillium expansum*, *Penicillium glaucum*, *Mucor mucedo*, *Aspergillus* sp., *Bacillus megatherium* (group), and *Micrococcus flavus* (group). When he was tested with these cultures, however, none of them

reacted Likewise, tests with a number of stock molds were all negative A flask was then inoculated with all of the molds and bacteria isolated from this patient's house dust "Scratch" tests with the dried felt and broth filtrate from this symbiotic mixture were completely negative

In all probability, therefore, Master R's reaction to house dust was due to ragweed pollen contained in the dust As a matter of fact, the specimen of dust had been collected shortly following the ragweed pollinating season As further proof of the correctness of this view, I would state that intensive ragweed treatment has made this boy entirely well of asthma

Case XIV E, a girl of 7 years, was referred to me with a history of bronchial trouble since infancy, and asthma for the preceding two or three years Skin tests showed a definite positive reaction to an extract of her own mattress dust, and slight or doubtful reactions to some foods and a few other substances which did not in any way explain her reaction to the mattress dust Tests with some of my stock molds were completely negative

Cultures of her mattress dust showed *Aspergillus glaucus*, *Penicillium chlorophanum*, *B. coli*, *Bacillus fluorescens*, and *Bacillus pyocyaneus* I have not yet had an opportunity to test E with these cultures, but her mattress was changed, and since then she has had definitely less asthma

Case XV Dr R, 43 years old, was referred to me with chronic bronchitis and asthma Cutaneous tests showed a slight reaction to cheese, and doubtful reactions to *Aspergillus hordei*, *Alternaria mali*, and *Saccharomyces* sp Tests with crude nonsterile extracts of his mattress and pillow dust were completely negative

Intradermal tests gave marked positive reactions to *Cephalothecium roseum*, *Aspergillus nidulans*, *Aspergillus parasiticus*, *Penicillium mixed*, and *Penicillium glaucum*, a moderate reaction to *Aspergillus niger*, and slight or doubtful reactions to *Mucor* sp, *Puccinomyces varioti*, *Aspergillus comensis*, *Alternaria mali*, *Aspergillus flavus*, and *Aspergillus fumigatus* All of these intradermal reactions, with the exception of a doubt-

ful immediate reaction to *Cephalothecium roseum*, were delayed, the interpretation being made the day following the tests The site of the *Cephalothecium roseum* test itched for a couple of days, and the skin desquamated over this area Also, the site of the *Aspergillus niger* test itched for two days These same mold preparations were tested intradermally on a nonallergic individual with completely negative results, proving that they were not nonspecifically irritating to normal skin

Case XVI Mr A, 53 years old, consulted me with chronic abdominal pain of undetermined cause Cutaneous tests with foods, bacteria, some of the more important stock molds, etc., were all completely negative

Culture of his stool showed *Aspergillus fumigatus*, but a "scratch" test with the culture of this mold was entirely negative Intradermal tests with *Aspergillus fumigatus* filtrate and extract gave slight or doubtful reactions Under treatment largely directed to changing this patient's abnormal intestinal flora, he has shown marked improvement, including a gain in weight of between 15 and 20 pounds Recent stool cultures were negative for *Aspergillus fumigatus*

Case XVII Mr L, aged 21 years, was referred to me with chronic brouchorrhoea, and hyperhidrosis of hands and feet In addition to the hyperhidrosis, his history and the appearance of his hands and feet were strongly suggestive of tinea

Thorough skin testing by the "scratch" method showed positive reactions to *Cephalothecium roseum*, *Trichophyton mixed*, *Trichophyton gypsum*, *Monilia* sp, and *Saccharomyces cerevisiae* There was no question about his sensitivity to *Cephalothecium roseum*, as he reacted to all of the preparations of this particular fungus, namely crude mold, dried felt, broth filtrate, and glycerin extract It is interesting to note that he gave immediate, urticarial reactions to *Trichophyton mixed* and *Trichophyton gypsum*

Cultures from twenty-four hour specimens of his sputum showed the following fungi: *Monilia sitophila*, *Aspergillus candidus*, *Aspergillus nidulans*, *Aspergillus niger*, *Aspergillus Wentii*, *Penicillium* sp, and *Saccharomyces torulae* The *Monilia sitophila* was

first thought to be *Cephalothecium roseum*, which would have checked up perfectly with his sensitization to *Cephalothecium*. Dr Thom showed me how *Monilia sitophila*, which is the common red bread mold, could be differentiated macroscopically from *Cephalothecium roseum* by their method of growth. *Monilia sitophila* tends to leave the medium and run up the side of the tube or flask containing it, whereas *Cephalothecium roseum* stays on the surface of the medium. Tests with sterile broth filtrates prepared from the *Monilia sitophila* were completely negative. Tests with crude cultures of the *Penicillium sp.* and *Saccharomyces torulae* were also negative.

As *Aspergillus candidus*, *Aspergillus Wentii*, and *Saccharomyces torulae* were not included in this patient's original tests with stock fungi, dried felt and broth filtrate have been prepared on each of these three fungi, and he will be tested with these preparations. Microscopic examination of scales from the skin of his hands was negative for fungi, but scales from his feet showed *Trichophyton interdigitale*.

The bronchorrhea and hyperhidrosis have shown some improvement under desensitizing injections of *Cephalothecium roseum* filtrate, starting with 0.1 cc of a 1:100 dilution. Intensive local treatment has been advised for the epidermophytosis of his feet.

Case XVIII Miss C, aged 38, had had asthma almost constantly for thirty years. She said that dust aggravated her trouble. She also gave a history of chronic constipation, and stated that almost everything she ate seemed to cause gas and bloating.

Cutaneous tests revealed a marked positive reaction to yeast (*Saccharomyces cerevisiae*), mild positive reactions to an extract of her own house dust, and *Mucor plumbeus*, and slight or doubtful reactions to *Penicillium glaucum*, *Penicillium lanosum*, *Alternaria mali*, *Mucor mucedo*, *Mucor circinelloides*, *Aspergillus comensis*, *Monilia sitophila*, *Mucor sp.*, mushroom (food), *Mucor* mixed, *Cephalothecium roseum*, *Penicillium griseo-roseum*, *Penicillium* mixed, *Trichoderma Konigii*, and an extract of her own bedroom carpet dust. A test with a crude extract of her own mattress dust was negative. Ex-

amination of her stool showed many *Blas-tocystis hominis*, which belongs to the yeast family.

Because of her marked sensitization to yeast, all foods containing this substance were eliminated from her diet, and a sterile 1:50 extract of the protein of *Saccharomyces cerevisiae* was prepared for treatment purposes. Desensitizing injections were started with 0.1 cc of a 1:50,000 dilution. Her most recent dose was 0.21 cc of a 1:50 dilution, but so far there has been little change in her asthma.

Case XIX Master H, aged 8 years, was referred to me with asthma of about 4 years' duration. Although his asthma was worse in the summer, he had it every day all the year around. The trouble was worse at night, and in damp, rainy weather.

"Scratch" tests showed a definite positive reaction to the dust from his own mattress, and slight or doubtful reactions to extracts of specimens of dust from two other mattresses in his home, and to *Monilia sp.* and *Endothia parasitica*. Tests with crude extracts of his bedroom rug dust, dust from a fourth mattress in his home, and his general house dust were negative.

His mattress was made of kapok, but he was not sensitive to this substance. It seemed, therefore, that his sensitivity to the dust from this mattress was probably due to some fungus that had gotten into the mattress. Cultures of a specimen of dust from this mattress showed *Aspergillus versicolor*, *Aspergillus clavatus*, *Mucor sp.*, *Aspergillus Wentii*, *Alternaria sp.*, *Bacillus subtilis* (group), *Bacillus anthracis*, *Bacillus megatherium*, *Bacillus mesentericus*, and an unidentified yeast or *Monilia*. Tests with these cultures were all negative, with the exception of *Aspergillus Wentii* which gave a slight or doubtful reaction. As *Aspergillus clavatus* and *A. Wentii* had not been included in this patient's original tests with stock molds, dried felt and broth filtrate were prepared from each of these *Aspergilli*, but tests with these preparations were negative. Also, tests were negative with the dried felt and broth filtrate from a symbiotic flask, which had been inoculated with all of the fungi and bacteria isolated from his mattress dust.

Another flask was inoculated with all of the fungi and bacteria from the mattress, and to this flask were also added some sterile kapok fiber and kapok-seed meal, to duplicate, as nearly as possible, conditions within his mattress. To insure sterility of the kapok fiber and seed meal, the fiber was obtained from a freshly opened kapok pod, and the meal was prepared by grinding dry kapok seeds after they were washed a number of times with ether. Master H was tested with the dried felt and broth filtrate prepared from this kapok treated symbiotic flask, with completely negative results. In addition to this, some moistened kapok-seed meal was inoculated with all of the fungi and bacteria cultured from his mattress dust, with the idea in mind that the micro-organisms might act on the kapok-seed protein to produce the allergenic substance present in the mattress dust. This mixture was allowed to stand for about a month, being remoistened when necessary, to favor free growth of the fungi. Then the mixture was dried, and tested on this patient, but gave absolutely no reaction. The reacting substance in his mattress dust is still an unknown quantity.

When it was discovered that he was sensitive to the dust from his mattress, this mattress was disposed of, and since then there has been a marked improvement in his asthma, and a gain in weight of 10 pounds.

Case XX Master B, 6 years of age, was referred to me with asthma. His first attack had followed a visit to Endless Caverns, which is a damp, moldy place. Last summer was spent at the seashore, and his asthma was much worse there than at home. In addition to the asthma, he sneezed and blew his nose most of the time.

Skin tests showed a positive reaction to *Alternaria mali*, and slight reactions to his own house dust and to dust obtained from the house at the seashore, the dust from the seashore house giving a little larger reaction than that from his own home. Tests with crude extracts of specimens of dust from his own mattress, pillows, day-bed, and upholstered chair were negative. Cultures from his own house dust showed *Alternaria* sp. and *Aspergillus fumigatus* as the predominating fungi, and also *Aspergillus glaucus*, *As-*

pergillus nidulans, *Aspergillus Wentii*, *Mucor* sp., *Penicillium expansum*, and *Penicillium italicum*. Tests with these cultures were all negative, with the exception of a positive reaction to the *Alternaria*. Cultures of dust from the seashore house revealed *Alternaria humicola* and *Aspergillus glaucus* as the predominating fungi, and also *Aspergillus fumigatus*, *Aspergillus niger*, *Aspergillus versicolor*, *Mucor mucedo*, *Mucor racemosus*, and *Penicillium expansum*. Tests with these cultures from the seashore house dust were all negative, with the exception of a definite positive reaction to the *Alternaria humicola*, and a slight or doubtful reaction to the *Mucor racemosus*.

As it seemed quite evident that his asthma was due to *Alternaria* sensitization, specific treatment was decided upon. The desensitizing injections were started with 0.1 cc of a 1:1,000 dilution of a broth filtrate of *Alternaria mali*. The doses have been gradually increased at weekly intervals, his most recent dose being 0.64 cc of a 1:100 dilution. Since the institution of this treatment, he has been almost entirely free of asthma. It is interesting to note, that after being free of asthma for some time, his parents took him for a week-end visit to the same house at the seashore. The first night he was there he started to sneeze, and the second night he developed asthma. This trouble left him when he returned home.

Case XXI Mrs. D, 52 years old, was referred to me with status asthmaticus. She had suffered from asthma constantly every day for the preceding twenty-six years. When she first came to me she was taking from ten to twelve hypodermics of morphine every twenty-four hours. She took $\frac{1}{4}$ gram at a dose, and a prescription for one hundred of these tablets would last her only eight to ten days. She also took hypodermics of adrenalin at intervals of thirty minutes to three hours. Damp weather aggravated her asthma, and dust also bothered her.

"Scratch" tests were all negative, with the exception of a doubtful immediate reaction to *Penicillium griseo-roseum*, and a slight or doubtful delayed reaction to *Monilia* sp. Cultures from her sputum revealed *Penicillium glaucum*, and from her stool *Asper-*

gillus niger, but neither of these molds reacted when she was tested with them

Intradermal tests showed slight or doubtful immediate reactions to *Penicillium* mixed and *Paecilomyces varioti*, and definitely positive delayed reactions to *Aspergillus nidulans* and *Paecilomyces varioti*, the former being a little larger than the latter. The site of the *Aspergillus nidulans* test itched a lot for twenty-four hours, which is a good diagnostic sign

Aspergillus nidulans, therefore, was selected for treatment, her first dose consisting of 0.1 cc of a 1:10 dilution of a broth filtrate of this mold. The doses are being gradually increased at weekly intervals. Although this patient is still having some asthma, she shows marked improvement, she has stopped the morphine entirely, and requires only an occasional hypodermic of adrenalin

Case XXII Mr P, 51 years old, was referred to me with facial eczema of about two years' duration. This trouble seemed to be worse in the summer. Cutaneous tests showed slight or doubtful reactions to the following fungi: *Mouha* sp (found in his stool), *Penicillium glaucum*, *Paecilomyces varioti*, *Mucor* mixed, *Alternaria mali*, and *Aspergillus glaucus*. Cultures from his skin lesions were negative for fungi. Under treatment largely directed to changing his abnormal intestinal flora, the skin trouble cleared up

Case XXIII Mrs H, was referred to me with perennial hay-fever, and recurrent eczema of her face, neck, and arms. She was worse in damp, foggy weather, and dust bothered her. Skin tests by the "scratch" method showed slight or doubtful reactions to cheese, and an *Aspergillus glaucus* was cultured from her sputum. A patch or contact test with this culture was negative. Skin tests with crude extracts of her own house and cellar dusts were negative. Cultures of the scales from her skin lesions revealed *Aspergillus glaucus*, *Mucor mucedo*, *Penicillium italicum*, *Sarcina*, and *Streptothrix*, but "scratch" tests with these cultures were all negative. If this patient cooperates sufficiently, patch tests will be done with the

three molds isolated from her skin cultures, and she will also be tested intradermally

Case XXIV Miss B, aged 42 years, was referred to me with chronic asthma. She was also troubled with gas and bloating most of the time. "Scratch" tests showed a marked positive reaction to *Saccharomyces cerevisiae* (yeast), and slight or doubtful reactions to grain smut, *Aspergillus glaucus*, and *Penicillium chrysogenum*. All foods containing yeast were eliminated from her diet, and the bloating promptly disappeared. Furthermore, she has had very little asthma since

COMMENT

Dr Thom has wisely said that "the *Penicillia*, the *Aspergilli*, and the *Mucors* are the weeds of the culture room". I would add that molds are the weeds of the home. Every specimen of house or mattress dust that has been cultured, was found to contain various fungi. The potentiality of molds being air-borne, may be appreciated if we compare the size of the ubiquitous spores with the size of pollen grains. The average diameter of mold spores is from 3 to 5 microns, whereas the diameter of the common air-borne pollen grains is from 15 to 40 microns

SUMMARY

This paper gives the results of an intensive study of sensitization to fungi, including a review of the literature, and the report of twenty-four illustrative cases

Sensitization to fungi must take its place along with sensitization to pollens, animal epidermals, foods, and bacteria in the causation of asthma, eczema, and other related allergic conditions

The method of diagnosing and treating hypersensitiveness to molds and yeasts is essentially the same as that used for other types of allergenic substances

Ten Years at the Lymanhurst School for Tuberculous Children

By J ARTHUR MYERS, M S , P H D , M D , F A C.P., *Minneapolis, Minn.*

NUMEROUS cross section studies of tuberculosis have been made In this paper is reported the first ten years of a longitudinal study undertaken at the Lymanhurst School for Tuberculous Children The chief value of the work at Lymanhurst has been in the opportunity to follow the cases over periods of years, and in so doing to write the history of their tuberculous lesions The medical staff engaged in this work is confident that the true story of tuberculosis in the human body has never been told and that it will not be told until this group or some other group of children is followed through the various decades of life; until death from some cause overtakes every one of them Many decades of work are to follow before ultimate conclusions can be drawn However, in ten years we have seen some developments of which we could never have been convinced except by

From the Departments of Preventive Medicine and Internal Medicine, University of Minnesota, and the Lymanhurst School for Tuberculous Children, Minneapolis, Minnesota

Prepared with the aid of a grant from the Medical Research Fund of the University of Minnesota

Presented before the Sixteenth Annual Meeting of the American College of Physicians, San Francisco, April 5, 1932

actual observation, inasmuch as they have been quite contrary to our former teachings

THE TUBERCULIN TEST

Each year our confidence in the tuberculin test has increased We have come to look upon it as the most specific test in the field of medicine While it is not infallible, we are of the opinion that when properly administered, it fails very rarely Of course, much depends upon the administration of tuberculin The epidermal test of Pirquet was in quite general use over a long period of time, but a number of workers, such as Smith and Hart, have called attention to the greater accuracy of the intracutaneous test of Mantoux In any work we undertake, accuracy is of prime importance, hence we are of the opinion that in tuberculin testing the intracutaneous test is the best and, therefore, should be generally employed Moreover, there is a great advantage in making the Mantoux the standard tuberculin test

At Lymanhurst we now administer 01 mgm of tuberculin as the first dose, and to all who react negatively, we repeat the test using a full milligram. Aronson has very carefully worked out this dosage and finds that in the most hypersensitive individuals no necrosis

or slough will follow the first dose. In none who reacts negatively to this dose will there be necrosis when a full milligram is administered.

When the child reacts positively to the tuberculin test, we are convinced that somewhere in his body there is tuberculosis and that from the development of this, in whatever stage it happens to be, hypersensitiveness to tuberculin or allergy has resulted. Therefore, the test is one for allergy and, so far as we know, not a test for immunity.

THE X-RAY

As soon as a tuberculin test is found to be positive, we seek the location of the focus of tuberculosis. In the body of the child, our best method of finding these foci is by the x-ray film examination, but even this is woefully lacking. By x-ray examination we located questionable to definite foci in 22.91 per cent of the positive tuberculin reactors. This is not surprising when one considers the nature of the

tuberculous focus, the numerous places in the body where it may occur, and the limitations of the x-ray as we now know it. Many tuberculous foci which cause positive tuberculin reactions are microscopic in size. Therefore, they are not detected by the x-ray. Some of them never become large enough to cast visible x-ray shadows. Others may grow to such size that they are easily detected.

Of the total number of children examined in the Out-patient Department at Lymanhurst School, 4,031 were negative to the tuberculin test. Unfortunately, in the early days of our work only the Pirquet test was used. Of this entire number, 90 (2.22 per cent) (table I) showed evidence of pleurisy. In only 2 was effusion definitely found and in another case there was a questionable small effusion. However, in 17 cases there was some thickening of the pleura over an entire lung, suggesting previous pleural effusions.

Of the total number of children examined in the Out-patient Department

TABLE I
Pleural Changes

	NUMBER	PER CENT
From 4,031 Negative Tuberculin Reactors		
Thickening of interlobar pleura	30	7.4
Diaphragmatic basal pleurisy	40	9.9
Thickening of pleura over entire lung	17	4.2
Pleurisy with effusion	2	0.5
Mediastinal empyema or effusion with thickened pleura	1	0.2
Total	90	2.22
From 4,737 Positive Tuberculin Reactors		
Thickening of interlobar pleura	59	1.25
Diaphragmatic and basal pleurisy	62	1.31
Thickened pleura over entire lung	33	7
Pleurisy with effusion	12	2.5
Rib resection	4	0.8
Total	170	3.59

at Lymanhurst School, 4,737 were positive to the tuberculin test Of this entire number 170 (3 59 per cent) (table I) showed evidence of pleurisy In 12 of these cases there was definite evidence of effusion In 4 cases rib resections had been done, and in 33 cases there was evidence of thickening of the pleura over an entire lung suggesting previous pleural effusions

Since our knowledge of the significance of the x-ray shadows in the hilum region is still incomplete, the roentgenologist must of necessity frequently make a diagnosis of questionable calcification Therefore, with such interpretations one must be extremely careful in following these cases over months or even years to determine whether calcium really is being deposited Among our negative tuberculin reactors, 44 (1 09 per cent) had questionable evidence of calcium in the hilum In 40 cases (99 per cent) there was evidence of slight and moderate

amounts of calcium in the lung hilum (table II) Evidence of Ghon tubercle formation was observed in 24 cases (60 per cent) In one case there were shadows interpreted as calcified nodes throughout both lungs We formerly looked upon such cases as healed miliary tuberculosis However, since Meriwether and Sayers have called attention to the possibilities of certain fungi, particularly aspergillus, resulting in such shadows, we are not certain of the etiology in this case

Among our 4,737 positive tuberculin reactors, 195 (4 12 per cent) (table II) were found to have questionable evidence of calcium in the lung hilum In 443 cases (9 35 per cent) there was evidence of slight, moderate and marked amounts of calcium in the lung hilum Ghon tubercle formation was observed in 286 cases (6 04 per cent) In 38 cases there was questionable evidence of Ghon tubercle formation Calcium in the lung hilum with

TABLE II
Questionable to Definite Childhood Type Tuberculosis

	NUMBER	PER CENT
From 4,031 Negative Tuberculin Reactors		
Questionable calcification in hilum	44	1 09
Slight and moderate calcification in hilum	40	99
Ghon tubercles	24	60
Calcified nodules throughout both lungs	1	02
Marked enlargement of hilum without calcium	4	09
Total	113	2 79
From 4,737 Positive Tuberculin Reactors		
Questionable calcification in hilum	195	4 12
Slight, moderate and marked calcification in hilum	443	9 35
Ghon tubercles	286	6 04
Questionable Ghon tubercles	38	8
Calcification hilum, fibrosis extending into lung parenchyma	26	55
Childhood type tuberculosis in lung parenchyma (inflammatory stage)	41	87
Marked enlargement hilum without calcification	18	38
Marked enlargement hilum-infiltration extending to parenchyma	38	8
Total	1,085	22 91

an area of fibrosis extending into the lung parenchyma was seen in 26 cases, while the childhood type of tuberculosis in the inflammatory stage, involving the lung parenchyma, was seen in 41 cases. In 18 of our patients there was marked enlargement of the hilum region without evidence of calcium. In another group of 38, such marked enlargement of the hilum region was seen without evidence of calcium, but there was parenchymal infiltration extending outward from the hilum into the lung parenchyma.

Thus among 4,031 children reacting negatively to the tuberculin test, only 113 (2.79 per cent) showed any evidence of the childhood type of tuberculosis and 44 (1.09 per cent) of this group had only questionable evidence, while among 4,737 cases reacting positively to the tuberculin test 1,085 (22.91 per cent) showed some evidence of

the childhood type of tuberculosis, although in 195 (4.12 per cent) of these cases the evidence was questionable.

Of the 4,031 children who reacted negatively to tuberculin, 2 cases (0.5 per cent) (table III) had far advanced pulmonary tuberculosis. The negative reaction in these two cases was obtained from the Pirquet test, since the administration of the Mantoux test had not been instituted at that time. Among the negative reactors were no cases of minimal or moderately advanced adult type of pulmonary tuberculosis. Among the 4,737 children who reacted positively to the tuberculin test the adult type of tuberculosis was found in 61 (1.28 per cent) (table III). Of this number the disease was minimal in extent in 24 (50 per cent), 17 of whom also had evidence of the childhood type. Moderately advanced disease was seen in 17 cases (36 per

TABLE III
Adult Type Pulmonary Tuberculosis

	NUMBER	PFR CENT
From 4,031 Negative Tuberculin Reactors		
Far Advanced	2	0.5
From 4,737 Positive Tuberculin Reactors		
Minimal (17 also had demonstrable childhood type)	24	5
Moderately advanced (11 also had demonstrable childhood type)	17	36
Far advanced (9 also had demonstrable childhood type)	20	42
Total	61	1.28
Tuberculosis of Bones and Joints		
From 4,031 Negative Tuberculin Reactors		
Bones and joints	None	
From 4,737 Positive Tuberculin Reactors		
Spine (6 with chest findings)	8	17
Hip joint (5 with chest findings, 1 with no chest examination)	12	25
Knee joint	3	0.6
Shoulder joint and ankle joint	1	0.2
Bones of hand (no chest examination)	1	0.2
Total	25	52

cent), 11 of whom also had evidence of the childhood type of the disease, while far advanced pulmonary tuberculosis was seen in 20 cases (42 per cent (table III), 9 of whom had evidence of the childhood type. It is interesting to note that there was coexisting childhood type of disease in 37 (60.65 per cent) of the cases with the adult type of tuberculosis.

Among 4,031 children reacting negatively to the tuberculin test, not one was found who had evidence of tuberculosis of the bones and joints. Among 4,737 children reacting positively to the tuberculin test, 25 (52 per cent) (table III) were found to have bone and joint involvement. Tuberculosis of the spine was seen in 8 cases, 3 of whom had evidence of childhood tuberculosis in the chest. Two others had pleural involvement and a third had an area of fibrosis extending outward from the hilum into the lung parenchyma. Thus 6 out of the 8 had demonstrable findings in the chest. In 12 cases there was tuberculosis of the hip joint. In 5 of these cases, there was evidence of childhood tuberculosis, one of whom also had moderately advanced adult type tuberculosis. In 3 cases there was tuberculosis of the knee joint, 2 of whom had evidence of childhood tuberculosis in the chest. In one case of tuberculous dactylitis no x-ray film of the chest was made.

Other abnormal conditions were found such as bronchiectasis, pulmonary abscess and pneumonia, which might justify making x-ray films routinely regardless of the tuberculin reaction. However, the number of lesions proved to be due to tuberculosis was quite small in our group, so small in

fact that we now feel it is a reasonably safe procedure to apply the tuberculin test, and make x-ray films only of those who react positively, except in those cases where there is some other special reason for x-ray films.

THE IMPORTANCE OF PROTECTION FROM ADDED INFECTION IN JUVENILE TUBERCULOSIS

If one observes a group of children who are negative to tuberculin over a considerable period of time, some of them if exposed, will become positive reactors. The work of Sir Robert Philip is an outstanding example of this procedure. Moreover, if one applies the Pirquet test or a small dose of tuberculin by the intracutaneous method and repeats the test with a full milligram of tuberculin by the intracutaneous method, one will find some positive to a milligram of tuberculin who were negative to the smaller dose. We have observed the tuberculin test change from negative to positive in 189 cases. There has been a great deal of discussion about whether a tuberculin test once positive ever becomes negative. We have seen the reaction change from positive to negative in 68 cases.

When we began our work at the Lymanhurst School, we were firmly convinced by reason of our previous teaching that the infant is unusually susceptible to tuberculosis and that he has almost no tolerance to tubercle bacilli. We were so convinced that our teachings had been based upon well-established facts that we rendered immediate grave prognoses in every case two years old or under who had evidence of parenchymal disease. We also rendered immediate grave prognoses

when a positive tuberculin reaction was found in the absence of demonstrable chest lesions in this age period. As time passed, we were chagrined to find that our prognoses were nearly always wrong. Most of the infants with parenchymal pathology did not even manifest symptoms of disease and practically none of those with positive tuberculin reactions ever fell ill. This led us to investigate more carefully the literature and determine upon what the previous teachings had been based. The majority of the reports in the literature were from groups of children in hospitals who were definitely ill from tuberculosis and who in reality were suffering from the adult type of disease, which is destructive in children. In the earlier literature, no one had studied over a period of years a group of symptom-free children either from the homes where there was much exposure or where there was no exposure, nor had anyone made serial x-ray films of the chests of such children. Krause made a careful study of the resistance of young and old guinea pigs from which he arrived at the following conclusions:

"1 When young and old guinea pigs are infected intracutaneously with relatively small quantities of virulent tubercle bacilli that are equal for all the animals there is an earlier appearance and more vigorous development of tubercle at the site of inoculation and in the regional lymph nodes in the old animals.

"2 After infection of this nature and heavy enough to cause generalized tuberculosis in the old animals, both young and old guinea pigs developed essentially the same grade of infection. There was nothing to indicate that the young were more susceptible than the old.

"3 When infected subcutaneously with

large quantities of virulent tubercle bacilli in equal dosage, a more extensive and progressive involvement resulted in the young than in the old.

"4 Since under these circumstances the young received per body weight double the quantity of tubercle bacilli that was in itself sufficient to cause progressive and fatal tuberculosis in the old, it is likely that the more advanced infection of the young was the result of overdosage."

Therefore, it would appear to be largely a matter of dosage rather than a matter of susceptibility to tubercle bacilli. Krause, from his wide experience with tuberculosis in man, together with his experimental work, makes the following statement:

"All in all, it is difficult to comprehend the logic of the frequently expressed warning that makes a sharp distinction between children and adults in respect to the dangers of exposure to tuberculous infection. It certainly is by no means clear that, person for person, the child is less resistant than the adult. As it works out in life, it is beyond dispute that the ravages of tuberculosis are in every way greater in later life than in childhood, and, even allowing for differences of environmental factors that determine illness, we would consider the proposition of a higher adult resistance as unproved. There are elements of resistance that would seem to be stronger in the child, there are other elements that appear more effective in the adult. Where the balance lies we do not know, nor may we assume to state. Quite likely it is an individual affair, and attempts to generalize promise to lead us into error.

"It would seem the better wisdom to presume not at all upon a resistance, and acquired immunity, that must be of undeterminable and hypothetical integrity in any particular case. We shall be following the larger science and come to a safer practical result if we adjudge children and adults alike before the hazards of tuberculous infection. The only rational attitude is to protect all human beings, of whatever age, against exposure. To allow the impression to get

abroad that adults walk within a charmed circle of acquired immunity, that maturity is a privileged age, can lead only to evil, if it is accepted and acted upon. Besides, there is much evidence that it may be far from the truth."

Myers and Kernkamp, working with Lymanhurst children who reacted positively to the tuberculin test at the age of two years or under, found that when they had traced 172 of these children, only 6 had died of tuberculosis. The majority of their group infected in infancy were apparently well at the time they were traced. These observations, together with the findings of others, led us to believe that our former teachings were wrong and that we must recognize the fact that the infant tolerates tubercle bacilli well, except in those cases where reinfection occurs frequently and in which the adult type of tuberculosis develops after allergy has been established. Many such cases die from generalized tuberculosis, including tuberculous meningitis. Therefore, the best treatment for any infant found to react positively to the tuberculin test is the prevention of subsequent exposure to tubercle bacilli. When this has been done, if the exposure has not already gone too far, the prognosis is excellent with practically no treatment or care beyond that which any normal child should receive. Because of this fact, which we feel is now well established, we are firmly convinced that the foster home free from tuberculosis is far better for the child in whose home open tuberculosis exists than the institution. The work of Bernard and others bears witness to the efficacy of this kind of treatment.

DOES FIRST INFECTION PROTECT?

Does first infection with tubercle bacilli protect against subsequent infection? This involves the subjects of immunity and allergy in tuberculosis, concerning which volumes have been written. In reading the literature, one gains the impression that a first infection is the best safeguard that we have against the destructive form of tuberculosis. Much is said about immunity, yet in all of our armamentarium, we have no definite test for immunity. The literature on this subject leaves one with many questions concerning which no answer can be found except those based on personal opinion. The fact that ten thousand children or adults react positively to the tuberculin test, and not one at that particular moment is ill from tuberculosis or has manifestations of tuberculosis in any of its clinical forms, is no safe criterion of immunity to the clinical forms of tuberculosis. In other words, it is only through subsequent observations, over not only years but decades, that one determines whether these ten thousand individuals were actually immunized. In observing children with positive tuberculin reactions through the first ten years of Lymanhurst's existence, our staff members have again been mistaken in the prognoses they render those beyond the period of infancy. We had been taught that if a child is infected after the period of infancy the prognosis is excellent and that the positive tuberculin reaction is an indication that he was well immunized against tuberculosis. When we saw evidence of lime deposits in the form of Ghon tubercles in the lung parenchyma or in the lymph

nodes in the region of the lung hilum and tracheo-bronchial lymph nodes, we rendered splendid prognoses because of the positive tuberculin reaction which to us, then, denoted immunity, and the child's ability to deposit lime which to us, then, denoted healing and vaccination against tuberculosis. When some of these children reached the 'teen ages and we saw developing in their lungs the adult and destructive type of disease, sometimes leading to death rather quickly in spite of everything that we knew by way of treatment, we began to investigate further the evidence upon which the statement concerning immunity to tuberculosis had been based. We could find nowhere in the literature that anyone had observed the same group of children throughout the various decades of life. Therefore, we

were at a loss to know how anyone had a right to the generalizations on this subject which were extant in the literature.

CASE REPORTS

The citation of five of the numerous cases which we have seen at Lymanhurst will illustrate this point. The very first child who entered the Lymanhurst School is such a case. On May 31, 1921, this boy was present at our dedication ceremony. There was clinical tuberculosis in his family. He was positive to the tuberculin test. He was rather thin and pale but he was suffering from a congenital disease which we believed accounted in part, at least, for his appearance. X-ray examination of his chest showed unmistakable evidence of lime deposits in the right lung hilum (figure 1). After a time he was discharged from the Lymanhurst School well immunized and vaccinated, as we thought. Approximately 10 years from the time he was admitted to the School, and when he was 22 years old, he walked into a

FIG 1 From an X-ray film taken November 21, 1922, of the chest of a boy of 12 years. Intimate contact exposure. Tuberculin test positive. Large calcium deposits in the region of the right lung hilum representing childhood type of tuberculosis. Same findings were shown on films made in 1921.

free chest clinic at the Minneapolis General Hospital and the examination revealed extensive pulmonary tuberculosis involving much of the left lung and a small portion of the right lung (figure 2). This was of the adult type and proved to be rapidly progressive. Neither the positive tuberculin reaction, nor the so-called vaccination scar, represented by calcium deposits in the right hilum, prevented the development of destructive tuberculosis or allayed the progress of his disease. Within a few weeks he was dead of tuberculosis. Thus our first Lymanhurst case, about whom we had talked and written so much and for whom we had rendered such an excellent prognosis based upon opinion not fact, shattered our teachings.

On October 27, 1925, a boy of 14 years was brought to the Lymanhurst Out-patient department for examination because of some cough and slight weight loss. There was no known history of exposure to tuberculosis in the family but both the maternal and pater-

nal grandparents suffered from asthma. The Pirquet test was only slightly positive. The examiner made the following note: "Persistent râles in the right apex after cough." The x-ray film showed considerable evidence of calcification in the region of the left lung hilum. Sputum examination was negative for tubercle bacilli. The temperature record was normal. On November 10, 1925, on re-examination no râles could be elicited. His temperature was normal, he was feeling well. One week later the x-ray examination showed no change. He did not report for re-examination but in the spring of 1932 he was a patient in the Glen Lake Sanatorium with frank pulmonary tuberculosis of the right lung with cavity formation.

In April of 1926 a girl of 11 years was brought to the Lymanhurst Out-patient department because of nervousness. There was no definite history of exposure to tuberculosis, but it was stated that her father was not well. The tuberculin test was markedly

FIG 2 From an x-ray film taken on November 6, 1931, of the same chest as seen in figure 1. Evidence of childhood tuberculosis in right lung hilum, as was seen in 1921 and 1922. In addition there is extensive pulmonary tuberculosis involving the greater part of the left lung and a small area in the fourth interspace on the right side.

positive The x-ray films of her chest showed definite evidence of calcification in the left hilum region, with Ghon tubercle formation in the extreme left base In the left apex was a small area of disease which had the appearance of the adult type of tuberculosis In December, 1928, there was no change in the x-ray film except an increase in the extent of adult type of tuberculosis in the left apex In May of 1930 this disease had extended so as to have become quite advanced and there was evidence of a fairly large cavity in the apex In June, 1930 artificial pneumothorax had been instituted

In July, 1927, a girl of 14 years was brought in for an examination because of exposure to her father who was then suffering from pulmonary tuberculosis The tuberculin test was slightly positive The x-ray film of her chest showed no evidence of disease except at the region of the left lung hilum This was interpreted as the childhood type of tuberculosis In February, 1929, there was a definite extension of this disease into the lung parenchyma, while in May, 1930, following blood spitting, there was definite increase of the shadow How much of this was due to hemorrhage could not at that time be definitely determined However, in December of the same year shadows were making their appearance in the upper part of the left lung In January, 1932, following phrenic exeresis performed at the Glen Lake Sanatorium, the left lung appeared very much improved

In May, 1928, a girl of 14 years was brought for an examination because of prolonged intimate contact exposure to a sister who was suffering from pulmonary tuberculosis There were no symptoms The x-ray film of her chest showed the childhood type of tuberculosis with beginning calcification in the left hilum region (figure 3) In July of 1930 she had an attack of pleurisy and during the same month she had a frank pulmonary hemorrhage X-ray examination of the chest in August, 1930 (figure 4), showed a definite adult type of tuberculosis involving the right lung In March, 1931, this disease was partly under control by artificial pneumothorax Disease later appeared in the left lung (figure 5) At this time, April, 1932

her general condition is good as she continues on bilateral artificial pneumothorax (figure 6)

A belief has been very firmly implanted in the minds of tuberculosis workers that it is good to have a positive tuberculin reaction by the time one reaches adult life In the literature one sees reference to the belief that it is an unfortunate individual who passes into adult life without a positive tuberculin reaction and then comes in contact with tubercle bacilli Opinion has it that it is such cases who develop military tuberculosis or galloping consumption More than a decade ago, I attended a national meeting where one of the world's outstanding authorities of the day discussed this subject In response to the question, if it were possible for a child to escape tuberculous infection and grow to adult life, say twenty or twenty-five years, still negative to the tuberculin test, what would be the outcome if he then came in contact with tubercle bacilli The answer was something like this That individual would be most unfortunate he would develop a rapidly progressive generalized tuberculosis and die of what is known to the public as galloping consumption Upon what scientific evidence was this statement based? Had any one followed such a case reacting negatively to the tuberculin test into adult life to observe the result? Apparently not So far as we have been able to determine the statement was based largely upon personal opinion

Changing conditions with reference to tuberculosis have brought about the time when tuberculous infection is not universal among young adults This fact gives us opportunities to study

FIG 3 From an x-ray film taken on May 14, 1928, of the chest of a girl of 14 years Intimate contact exposure Tuberculin test positive Childhood tuberculosis with beginning calcification in the left hilum region

FIG 4. From an x-ray film taken on August 26, 1930, of the same chest as figure 3 Childhood tuberculosis of left hilum region The adult type of tuberculosis has now made its appearance in the right lung.

FIG 5 From an x-ray film taken on October 6, 1931, of the same chest as figures 3 and 4. Artificial pneumothorax has been instituted on the right side and disease of the adult type has made its appearance in the left lung.

FIG 6 From an x-ray film taken on December 1, 1931, of the same chest as figures 3, 4, and 5, after artificial pneumothorax had also been instituted on the left side.

those persons who react negatively until they reach adult life. There are now communities, in fact, we believe good sized areas in the United States, where such individuals may pass through life's span without becoming infected with tubercle bacilli. Certain of these individuals enter hazardous occupations and professions. In other words, in the preparation for certain professions they are greatly exposed to tuberculosis. I refer particularly to the nursing and the medical professions. Here we have been able to observe young adults entering schools of nursing and medicine with negative tuberculin reactions and to test them with tuberculin and examine them by x-ray films periodically. Over and over we have seen the students of nursing and medicine reach the junior or senior years with negative tuberculin reactions, then following exposure to tuberculous patients some of them present positive tuberculin reactions. Usually they are positive to a three plus degree with a 0.1 mgm of tuberculin, indicating a high degree of allergy. At this time the x-ray film examination is usually negative. As time passes, however, often in the complete absence of symptoms, there appear in the chests of some of these recently positive reactors definite evidences of disease. If the focus is in the lung parenchyma, it may remain small or there may develop around it a considerable area of collateral inflammation. So far as we have been able to determine, the lesions are not apparently different than those we have observed develop from the first infection with tubercle bacilli in the chests of infants and children. From our series, however, we are inclined to believe that

pleurisy with effusion occurs somewhat more frequently in young adults than in children. However, our series is not sufficiently large nor have our observations been made over a sufficiently long period of time to make a final statement on this point. Suffice it to say that in the group we are following, we have not seen one patient develop galloping consumption.

CLASSIFICATIONS

When Lymanhurst began, there were many names in use for lesions produced by first infection type of tuberculosis. Such names as juvenile tuberculosis, primary complex, Ghon tubercle, hilum tuberculosis, tracheo-bronchial lymph node tuberculosis, and epi-tuberculosis were in use. The result was that confusion reigned. No one was entirely certain as to what type of case other workers were considering. A special committee of the American Sanatorium Association in 1929, adopted the term, "childhood type of tuberculosis," and gave definite description of this type. Since that time we have had a common name which is aiding greatly in arriving at a better understanding of the first infection type of tuberculosis. At Lymanhurst, we reclassified our records. Our present classification consists of:

1. Negative to tuberculosis. In this group are placed those children who are negative to the tuberculin test when a full milligram of tuberculin has been administered intracutaneously, and who have no other abnormal findings due to tuberculosis.

2. Primary tuberculous infection. This group consists of those children who react positively to the tuberculin

test but in whom no evidence by x-ray, physical, or laboratory examinations can be obtained of tuberculous disease. We feel certain that each of them has a lesion and in reality, therefore, has tuberculous disease, but by our present methods of examination we are not able to demonstrate its location.

3 Childhood type of tuberculosis. In this group the children react positively to the tuberculin test and in addition have some evidence, usually by x-ray, of the location of the focus or the foci. The lesion may be represented by a shadow indicating an inflammatory process which is progressing, stationary, or receding. Again it may be represented by shadows indicating deposits of calcium. These lesions need not necessarily be in the chest. When evidence of calcium deposits is found in lymph nodes anywhere, particularly in the cervical region or in the mesentery, the classification is that of childhood or first infection type of tuberculosis.

(a) Those with the inflammatory stage when we first see them, progressing, stationary, or receding. If receding, some workers speak of them as the resolving childhood type of tuberculosis. Clinical activity and progression of such lesions are difficult to determine at the first examination, since, in our experience, the most of them have caused few or no symptoms. Of course, they are all active pathologically.

(b) Consists of those lesions in which deposits of calcium can be demonstrated by x-ray film examination. At one time, we spoke of these as healed tuberculous lesions but observation has led us to believe that no

one but the pathologist can make such a diagnosis. Pathologists have pointed out repeatedly that the deposits of lime which we formerly believed actually encased and walled off foci of tuberculosis are usually surrounded by caseous material. Therefore, we never give a case with such a finding a better rating than latent. There may exist an interval of considerable time between *a* and *b*, when the x-ray film examination is almost or entirely negative. If the child is examined for the first time during this interval, there is a strong likelihood that the x-ray report will be negative. At some subsequent time, the x-ray will show deposits of calcium in the area formerly occupied by the disease in its inflammatory stage in the lung parenchyma and in the regional lymph nodes about the lung hilum. The time interval between the development of the inflammatory process and the almost simultaneous enlargement of the regional lymph nodes and the deposition of calcium in these lesions varies a great deal with the individual. The shortest period of time I have seen reported in the literature, is four months. In most of our cases a much longer interval has existed.

4 Adult type of tuberculosis. In this group, we have placed all of the definite clinical forms of tuberculosis whether the lesions appear in the lungs, bony framework, or elsewhere.

Thus we use only four groupings as far as diagnosis is concerned. From the standpoint of the stage of disease and activity, we subdivide group 3 into those with the childhood type of tuberculosis *a* and *b*. We have subdivided the cases with pulmonary tuberculosis according to the classification

adopted by the American Sanatorium Association and by the National Tuberculosis Association

We are dissatisfied with the terminology of the second division. We are so firmly convinced of the specificity of the tuberculin test that we feel that every child reacting positively has in his body somewhere, a tuberculous focus. Although our methods of examination are not sufficiently refined to locate many of these foci in the living body, nevertheless, we are convinced of their presence. Therefore, we are of the opinion that every one of these cases should be classed as a case of the first infection or childhood type of tuberculosis without demonstrable lesions. A place in our classification with a sharp line between so-called tuberculous infection and tuberculous disease is not warranted by our experience. We believe that work in tuberculosis control has been definitely retarded because of this sharp dividing line. How easy it is to examine a child who has reacted positively to tuberculin and fail to find any symptoms or evidence of disease even by stereoscopic x-ray films, and then pass over the condition lightly by saying, "This means nothing except that the child has been infected!" In reality, it means that there is a focus of disease present which may have resulted in no symptoms or symptoms so subliminal as not to have been detected, or mild detectable symptoms which were mistaken for those of some other disease condition. In our opinion, it is better to face the issue squarely and recognize the existence of foci of tuberculosis in all cases reacting positively to the tuberculin test. It

then becomes a question of extent of lesion. Fortunately for the human family, many such lesions apparently are never greater than microscopic in proportion, therefore, are never demonstrated in the living body, but in a certain percentage of cases, and no one knows with certainty what this percentage is, the lesions become macroscopic in size and if located in a part of the body which lends itself to x-ray film examination, will cause a shadow which can be demonstrated on the x-ray film. Such cases, then, fall into group 3. In some cases reacting positively to the tuberculin test whether the first infection type lesion is or is not demonstrable, there later appears the destructive type of tuberculosis, which classes them in group 4.

We now admit to the Lymanhurst School those children who have the childhood type of tuberculosis and minimal lesions of the adult type, provided such cases are not spreaders of tubercle bacilli. We are of the opinion that children who have recently become positive reactors to tuberculin should have the advantage of such an institution.

The Lymanhurst School does not provide the last three years of high school. Inasmuch as it is during the high school age that so many children fall ill with the adult type of tuberculosis, we believe that such a school should include all the grades through high school. However, since in the latter part of the high school course most children are beyond the compulsory school age, the problem becomes complicated.

In the Lymanhurst School the treatment is very simple. This institution is

a day school and no provisions are made for any child to remain longer than the usual school hours. When a child is admitted the first thought is to prevent further exposure to tuberculosis. If an open case exists in the home, one can not expect good results until the contact is broken. This must be considered the first principle in the treatment of the childhood type of tuberculosis. Careful attention is paid to the diet, in order to insure a sufficient amount of growth-promoting, energy-producing, and tissue-building foods. Cod liver oil is used as a food in order to insure a sufficient amount of vitamins A and D. After providing foods to provide energy, an attempt is next made to conserve it through the regulation of games at the recess periods and through a special rest hour immediately after lunch. Close medical and nursing supervision are provided, as we feel this is second only to the regulation of energy expenditure. Through ten years of observation of cases with the childhood type of tuberculosis, we are convinced that institutional care such as that provided by the sanatorium or general hospital is not necessary nor do we believe that special methods of treatment such as collapse therapy are indicated in the childhood type of tuberculosis. When our children develop the adult type of disease, however, we are of the opinion that the most drastic methods of treatment now employed should be instituted. We thoroughly agree with Chadwick in the use of collapse therapy even in minimal cases of the adult type of tuberculosis in girls and boys of the 'teen ages. When such cases develop and show a tendency

to spread and to break down, we refer them to their private physicians if they are able to pay for medical care, otherwise, they are referred to the University of Minnesota Hospital, the Glen Lake Sanatorium, and the Minnesota State Sanatorium. When they have been satisfactorily treated they may then return to Lymanhurst to complete the grades taught there.

SUMMARY

1 In the diagnosis of the childhood type of tuberculosis the tuberculin test and x-ray film examination are superior to all other aids.

2 The best type of tuberculin test is the intracutaneous method of Mantoux, inasmuch as its administration results in a greater number of positive reactors and it allows a measure of the dose of tuberculin.

3 Observations at Lymanhurst lead us to believe that the intracutaneous test is so specific that it constitutes a very fine tuberculosis screen. Therefore, it can be used to great advantage in the selection of children for further studies. If the tuberculin test is negative to a full milligram of tuberculin, one need go no further as far as tuberculosis is concerned, except in rare cases. If it is positive, one should then seek the location of the disease.

4 The x-ray film aids us in locating more foci of tuberculosis in the human body than all other phases of the examination combined. Indeed, it is the only phase of the examination which locates the childhood type of tuberculosis in any considerable number of cases.

5 The x-ray film is a coarse screen when compared with tuberculin inas-

much as we are rarely able to detect lesions by its use in more than 20 to 25 per cent of the children who react positively to this test

6 Among 4,031 children reacting negatively to the tuberculin test, there was evidence of questionable to definite childhood type of tuberculosis in 2.79 per cent while among 4,737 children reacting positively to the tuberculin test, such evidence of the childhood type of tuberculosis was found in 22.91 per cent. Among the 4,031 negative tuberculin reactors the adult type of tuberculosis was found in .05 per cent, while among the 4,737 positive reactors the adult type of disease was found in 1.26 per cent. Among our negative tuberculin reactors, no case of tuberculosis of the bones and joints was found, while among the positive reactors 52 per cent was found.

7 In our experience the infant has been found to have an excellent tolerance for tubercle bacilli. The factors which seem to determine whether he survives or succumbs are dosage and continued exposure.

9 Our observations have convinced us that only those children with the first infection type of tuberculosis develop the adult and destructive type. Therefore, we can not see our way clear to consider the first infection type of tuberculosis as a protection to the child.

10 In a group of young adults re-

acting negatively to the tuberculin test, who became positive reactors following exposure to tuberculosis, we have been able to watch the lesions make their appearance on the x-ray film and to follow them. This group has convinced us that such cases, reaching adult life before becoming infected with tubercle bacilli, do not develop galloping consumption as was formerly thought. Therefore, in our opinion the longer the first infection type of tuberculosis can be prevented in the human body, the better. The ultimate goal should be to reduce the possibilities of exposure so that the span of life may be lived without the first infection type of tuberculosis appearing in the bodies of most people.

11 The childhood type of tuberculosis usually comes under control without treatment. We believe that it rarely, if ever, kills as it occurs in nature, and we are of the opinion that the vast majority of such cases do not require hospitalization. Protection from further exposure to tubercle bacilli, energy producing foods, conservation of energy, medical and nursing supervision, such as may be provided by special schools for tuberculous children, is all that is required. When the adult type of tuberculosis appears, if the home conditions are not good, sanatorium or hospital care is indicated, and such special treatment as collapse therapy is none too drastic.

Friction Rub over the Liver in a Patient with Subacute Bacterial Endocarditis

By MILOSH KASICH, M D, *New York, N Y*

THE patient, B S, 15 years of age was admitted to the New York City Hospital March 21, 1930, complaining of pain in the chest, cough and shortness of breath. The family history was unimportant. He had been an invalid since childhood and when he was two years old his mother was told that he had "heart trouble." For many years his activity had been limited because of dyspnea upon the slightest exertion. There was no history of rheumatic fever or of chorea. He had had occasional sore throats. Tonsillectomy was performed about five years ago.

His present illness began about five months before admission. Dyspnea, which had always been present to some extent, became more severe, and grew progressively worse. He had been bed-ridden for the last two weeks. Several days before he began to complain of pain in the right chest, and in the right upper quadrant. The abdominal pain was described as burning in character. A distressing cough, with blood streaked sputum, had been present for the last week. The pain in the chest was aggravated by coughing.

Physical Examination An acutely ill, undernourished boy, lay propped up in bed, breathing with difficulty. Eyes, ears, nose and throat were negative. The veins in the neck pulsated. Anteriorly, both lungs were clear. There was a friction rub in the right axilla. Both bases posteriorly were dull. The precordium was bulging and a diffuse impulse was felt along the left sternal margin. The apex was in the sixth interspace, 11 cm from the midsternal line. A double murmur, heard best in the region of the apex, was transmitted over the entire precordium. The rate of the heart was 128, and regular. The blood pressure was 110/55. The abdomen was soft and not distended. The liver was felt two fingers below the right costal margin, it was not tender and did not pulsate. The spleen was not palpable. The fingers were slightly clubbed. There was no ankle edema. Knee jerks were equally active. Examination of the blood showed Red blood cells, 4,050,000, hemoglobin, 75 per cent, white blood cells, 14,000, polymorphonuclears, 75 per cent, lymphocytes, 25 per cent. The roentgen-ray examination of the chest showed marked stasis of the pulmonary fields with some areas of consolidation at the right base broncho-pneumonic in type. The heart

From The City Hospital, New York, N Y

Received for publication, December 16, 1931

shadow was typical of mitral stenosis.

The diagnosis made at the time was Chronic rheumatic endocarditis, adhesive pleurisy, bronchopneumonia, subacute bacterial endocarditis with pulmonary infarction

Progress of the Case. The boy was put at complete rest. He was given a light diet, forced fluids and sodium salicylate, 20 grains three times a day. His condition remained essentially unchanged. The temperature was intermittently febrile in character, rising to 104.4° C, and occasionally falling to 99°. On March 26 an area of consolidation was found on the left side in the posterior axillary line. On April 4 the patient was much improved. The chest signs, however, did not clear up. On several occasions he expectorated small amounts of blood, and twice developed red, painful joints, the knees and elbows being involved. He frequently complained of substernal pain. Blood culture on April 26 was negative. The urine was frequently examined for red cells, but none were found. On May 1 another blood culture was taken which also proved negative. On May 18 it was noted that the fever was continuing, the liver was larger and more tender. The splenic area was tender on percussion, suggesting either infarction or intense congestion. Although a positive blood culture, petechiae, and a palpable spleen were lacking numerous infarctions in the lungs and spleen and the continued irregular fever pointed to subacute bacterial endocarditis. On June 5, at a point two inches to the left and three inches above the umbilicus a loud friction rub was heard. This area corresponded to the enlarged right lobe of

the liver. The sound was influenced by both the heart beat and by respiration and was localized over an area about the size of a twenty-five cent piece. The entire liver was very tender and the abdominal muscles were rigid.

The patient lost ground steadily and died on the morning of June 7.

Autopsy (Dr. James Lisa) The chief findings at autopsy may be summarized as follows:

- 1 Chronic rheumatic endocarditis, with stenosis of the mitral and tricuspid valves
- 2 Subacute bacterial endocarditis, with many hemorrhagic areas over the endocardium
3. Marked atherosclerosis of the pulmonary artery
- 4 Multiple areas of infarction in both lungs
- 5 On the upper surface of the right lobe of the liver almost in the midline, there was an area about the size of a silver dollar, dull, and covered with fibrinous exudate. The corresponding area of the parietal peritoneum showed a similar change.
- 6 Chronic congestion of the spleen with no infarction demonstrable.

SUMMARY

A case of subacute bacterial endocarditis is reported which during the course of the disease developed a friction rub over the liver. Post-mortem examination showed the rub to be due to an area of peritonitis over the liver. The mechanism of the production of the sign is most probably a metastatic hematogenous infection. Such a finding has not been previously reported.

The Migraine Syndrome

By OLIVER T. OSBORNE, M A , M D , F A C P , *New Haven, Connecticut*

A VERY interesting research on migraine by R. M Balyeat and H J Rinkel (*ANNALS OF INTERNAL MEDICINE*, 1931, v, 713-728) causes me to offer the results of my long study of the causative factors of this painful disease or syndrome. Also, I believe that we should study this syndrome from all angles.

In the first place, I agree with the above writers that the cyclic vomiting of young children is a migraine symptom. Secondly, I also find that those afflicted with migraine very commonly have their attacks become less frequent or entirely disappear after about forty-five years of age. I attribute the cessation of the migraine at this time to presbyopia and the consequent use of glasses that relieve eyestrain.

So-called migraine is a condition that may be defined as a pain which begins at one side of the head, and is often termed "sick headache" because it is associated very generally with nausea and vomiting. These attacks are likely to occur periodically, more or less regularly. It is a question whether this kind of headache should have a distinct name. It is not an entity but a syndrome. It has been considered a neurosis, and it is true that people with a neurotic tendency are more likely to have this sort of headache than are phlegmatic individuals. In the writer's

opinion, in the vast majority of cases of so-called migraine imperfect eyes, and therefore eyestrain, is the cause. In fact, after forty-five years of practice as an internist (half of which time was spent in general practice and the latter half as consultant in internal medicine) he has never seen a case of typical migraine that did not have optic defects and consequent eyestrain as a cause.

Migraine is said to be hereditary, as a matter of fact it is only the neurotic tendency and defective eyes that are handed down in families. The type of eye that is inherited is astigmatic, most frequently associated with hypermetropia, and such defects cause eyestrain and consequent headaches. This type of headache is very likely to begin in early childhood, especially when the child first goes to school.

These headaches are referred to every cause that can be considered except the one to which it is due, namely, eyestrain. There is no question that overeating, indigestion, constipation, hyperexcitability, increased thyroid secretion, fever from any cause, disturbances at the beginning of menstruation, mental excitement, or anything else that is abnormal or excessive will cause a headache in these individuals. But the reason they cause a headache in these persons lies in the presence of optical de-

fects, and the reason that the pain generally occurs more on one side of the head than on the other is because the eye on that side is more defective and there is a greater strain of the eye muscles on that side. Late hours and prolonged use of the eyes will precipitate an attack of headache, generally the next morning.

Nasal pressure, adenoids and disturbances of the ear may all aid in causing so-called migraine. Also there is a great tendency to periodicity, possibly from coincident pituitary disturbance. This periodicity may be so imbedded in the constitution of the individual that no matter what is done toward correcting the eye defect, recurrences of the migraine will take place. Therefore the sooner in the life of the individual the eye defect is corrected, the less likely are such attacks to recur, *provided the correction is perfect*.

While migraine has been so long considered a distinct disease of the nervous system because there are so many associated symptoms that are not headache, still, a study of the eye reflexes will show that they are all dependent upon an abnormal condition in one or both eyes.

The time of day and the particular irritant, or disturbance, that starts the eyestrain headache varies with the individual. Some wake up in the morning with their headache from the eyestrain of the day before. Others have the headache in the later part of the day and it stops soon after the individual goes to bed. Others have their headaches begin in the morning and grow gradually worse until they are completely prostrated.

Probably the most frequent cause of intense eyestrain headache is astigmatism, generally that which is associated with hypermetropia. Hypermetropia alone can give recurrent headaches, and myopia less frequently. Not infrequently, the greater the defect, the less frequent the headaches, because the eye may refuse to correct the image, or the image of one eye may be entirely eliminated, the patient using only one eye and ceasing to attempt binocular vision. Therefore, many times the person with a minor optic defect, whose eye muscles always strive to give him a perfect image, is the one who has the most eyestrain headaches.

A frequent prodromal symptom of an attack is a craving for food, a sort of hunger, and frequently a hunger for meat. This is the same reflex which, after the headache begins, goes to the other extreme and causes nausea and vomiting. In the intermediate time between the craving for food and the nausea and vomiting, digestion is inhibited and food may lie in the stomach for hours, to be finally vomited, undigested, often with excessive acidity and with regurgitated bile.

Any prolonged, close use of the eyes without normal intermission, as working for hours without food, reading late in the evening, playing cards; embroidering or sewing too long, going to the theater or movies, or anything that uses the eyes for long periods of time without rest, will cause these individuals to have a headache. Many persons, even if glasses that correct the eye defects are worn have headache from the above causes.

Sometimes this "eye tire" is corrected before it has gone too far by

eating some simple food, the blood goes to the digestive organs and the head is relieved of congestion and tire. Some individuals can not eat at all, and will lose their appetite entirely, with the least headache.

Sometimes the most intense headache is caused by distance vision, as when the individual goes into the mountains and looks up a great deal, or when he goes to the seashore, or is on the water, and watches the waves.

It is very easy to determine that the headache is due to eyetire by careful questioning.

First, what is the patient's work, how long does he use his eyes, what does he like to do and what does he dislike to do, does going to the movies, to the theater or to church cause headache, does reading the poor print of the newspapers, playing cards, sewing or other eye-work cause headache, does he become car-sick, or trolley-sick or is he rested by riding, does he get a headache at a ball game or by watching a parade, does she get a headache from shopping? The study of the answers to all of these questions will convince the interrogator that he is, or is not, dealing with an optic defect.

The majority of individuals, until they have learned that their headaches are due to eyestrain, attribute the headache to almost anything they may have done last or eaten last. They change their diets, they omit this or that food, or they call it nervous tire and nervous headache, or they lay the headache to some condition, as bad air, or being shut up and not getting out-of-doors, or to menstruation, or to most any of the things that occur in life. While these are doubtless aggravating

factors, the headache would rarely occur if eyestrain were not present.

Some peculiar cases do not have headache with defective eyes, but have stomach reflexes of all kinds and descriptions, indigestion, flatulence, pyrosis or hyperacidity, or they have cardiac disturbances, as faintness, palpitation, or irregularity of the heart beats. They may be treated for these conditions by washing out the stomach, by heart tonics, etc., etc., when the cause is really and only, many times, eyestrain, which, when corrected causes these abnormal symptoms to disappear.

The most intense eyestrain headaches, migraine attacks, are caused by astigmatism, and the muscles most concerned with correcting abnormal meridians of the eye are the superior and inferior oblique. These rotate the eye so that even with imperfect rotundity a perfect image is seen. The superior oblique muscle goes to the upper internal angle of the orbit, and thus is a point, very generally, of intense pain in eyestrain headache, showing that this muscle becomes tired and irritated and apparently goes into spasm much as a wry-neck or other muscle cramp. The inferior oblique goes backward and out beneath the inferior rectus muscle, and is inserted in the sclerotic membrane between the optic nerve entrance and the attachment of the external rectus. When this muscle is strained the pain seems to be more deeply seated back of the eye, and it also, doubtless, goes into a condition of cramp or spasm.

As above stated, this eyestrain headache may be confined to one eye, but more frequently it goes to the other eye.

in sympathy, or the other eye may also have defects, but as generally one eye is worse than the other, the headaches are likely to start as a one-sided condition.

Depending entirely on the intensity of the spasm and the pain and the neurotic tendency of the individual, other nerves take part in the paroxysm, and there may be pains in the nose, in the face or around the ear, and frequently there are pains in the back of the neck, and even sometimes down the spine, with slight stiffening of the muscles of the back of the neck, showing the great seriousness of reflex conditions from the hypersensitive nerves of the eye. The pain may be so severe as to cause groaning. Sometimes, even in the beginning, it is so intense as to cause faintness and a weak pulse, especially if mental control of the condition is continued too long without going to bed and completely relaxing. When this autosuggestive control lets up and the patient gives in, the pain seems more intense for a time. Sooner or later, in many patients, nausea and vomiting occur, and the patient is said to have a "sick headache", which is laid to something that he has eaten, which can be only a contributory cause to this kind of a headache.

Many individuals learn to take a quickly acting cathartic, and after it has acted, as the headache soon stops, they attribute the condition entirely to gastro-intestinal disturbance and to constipation. While there is no question that benefit occurs from free action of the bowels as well as from evacuating the stomach, in relieving congestion in the head, constipation is not the cause of this kind of headache. Headaches from constipation are of the

dull variety, are more general and are never intense. The same is true of liver insufficiency headache.

The patients who vomit profusely and have terrible nausea and retching become very faint, pale and almost pulseless at times. Soon after this condition occurs the pain will generally cease, relaxation of the muscles occurring, the spasm stopping, and the head is relieved. Sometimes, therefore, the more intense the vomiting the quicker the "migraine" is over. How absurd it is to consider that the stomach condition had anything to do with the cause of the headache is shown by the fact that these individuals can, within a short time, sometimes in an hour or two, eat a good meal, enjoy it and retain it.

Those individuals who have eyestrain headaches without nausea and vomiting can generally keep about all day and fight the headache, and if their glasses are correct, or if they change glasses to those that are correct, may even get over the headache while continuing to work.

Many of those with even a mild form of this headache have cold hands and feet while the headache is in evidence, showing vasomotor spasm. It is quite possible that some of these headaches occur with some of Raynaud's syndrome symptoms. Spasm of blood-vessels may occur as well as the muscle cramp of the eye muscles.

During or preceding these headaches there is frequently an increased amount of urine passed. The urine may be hyperacid, and is generally of low specific gravity. The surface of the body is often cold at the same time, showing contraction of peripheral bloodvessels.

Before the onset of the eyestrain headache there seems to be a tendency to hyperacidity of the system, often stomach hyperacidity, and extra-acid urine, with probably a lessened alkalinity of the blood. Hence it is advisable when premonitory symptoms of these headaches are developing to give a cathartic and to push alkaline treatment.

To repeat, in eyestrain headache or migraine there is often spasm of the oblique muscles of the eye and probably frequently a spasm of the blood vessels of the eye and other parts. This is the reason that anything that reduces this spasmodic condition of the muscles or bloodvessels improves or stops the headache, therefore the advantage of coal-tar drugs. Antipyrine, acetanilid, phenacetin, pyramidon and aspirin are the drugs that enter largely into all patented medicines that are sold to cure headaches. Many a sufferer from headache acquires a habit of taking one or more of these drugs, to his or her detriment, as they are all more or less debilitating, all weaken the heart, all tend to cause anemia, and all are muscle depressants. Of course any strong narcotic will stop the headache, as morphine or codeine. Some persons have even inhaled chloroform to stop the terrible pain from an eyestrain headache.

Nature's method of terminating such a headache, when not assisted by drugs, is by the profound nausea causing sufficient muscle relaxation and circulatory depression to relax the spasm of the bloodvessels and muscles that are in trouble. Sometimes the headache ceases almost magically, almost instantaneously. At other times the pain

gradually disappears. If nausea and vomiting do not occur, a hot foot bath to take the blood from the head, or hot water bags around the body, or a hot water bag directly over an eye may cause relaxation sufficient to relieve the spasm and stop the headache. Some individuals learn to take a large dose of alcohol and obtain relaxation of the spasm and dilatation of peripheral vessels, and in this manner get relief.

Some milder forms of this headache last all day until the sun goes down and the light is less, and then relaxation occurs and the headache ceases. Others who do not have vomiting with the attack have the headache persist until after a night's sleep. Most patients during this kind of headache seek a dark room and wish perfect quiet, hardly desiring anyone to speak to them, unless they have serious cardiac depression, almost a syncope, when they wish assistance. They are even so faint, sometimes, that they feel they may die. Such prostration and cardiac weakness may be helped by large doses of alcohol, especially gin, or by black coffee, if they are retained.

Sometimes excruciating pain is helped only by a hypodermic of morphine. Of course such treatment is reprehensible, lest a habit be formed, but the intensity of the pain and the reflex action on the heart, almost to the point of heart failure, occasionally requires such treatment.

Not infrequently an effervescent mixture of phenacetin or other coal-tar drug, or a dose of aspirin, or of a coal-tar depressant combined with caffeine will help headaches, and many patients become addicted to taking bromoseltzer.

Curative treatment of the condition means the determination of the exact cause, and since the most frequent cause is eyestrain, an absolute correction of the optic defect, that is *correct* glasses, in *correct* frames, *correctly* worn will make the headaches infrequent, and in many cases cure the condition

The oculist should ascertain the kind of work the individual does, and determine what kind of glasses (especially when presbyopia is present) should be given the person, and whether he shall wear the glasses for near work only or all the time. All this must be carefully determined. The lenses must be perfectly ground, the frames perfectly fitted to the face, and if the individual has astigmatism probably the glasses must be worn constantly. The kind of frames is important. They must not be such as readily get out of adjustment. The patient should be told by both oculist and optician and by his physician that maladjusted lenses are as bad as no lenses at all, or even worse,

that his glasses must be frequently re-adjusted, that his eyes will change, and that in from a few months to a year or two, he will probably need a change of lenses

It is also essential that the patient should understand that the oculist's science is not entirely an exact one, and that he may not be able to determine the correct lenses at first, any more than the physician is able to find at the first visit the exact treatment advisable for some internal condition

In the majority of instances (and it should be noted that eyestrain headaches begin during childhood in a large number of cases) the headaches will be cured by proper glasses. Frequently most of the dissociated reflex effects, such as indigestion and heart upsets, are cured by correct lenses

It must not be forgotten, however, with the above emphasis upon eyestrain, that many headaches are due to endocrine gland disturbances, and that correction of these insufficiencies prevents the headaches

The Trend in Cerebral Localization

By LEWELLYS F. BARKER, M.D., F.A.C.P., *Baltimore, Maryland*

THERE is no more fascinating subject in the whole of medicine than the study of the activities of the human brain. This topic has engaged the interests of some of the best workers in medicine—anatomists, physiologists, clinicians, pathologists, experimental workers, psychologists—especially during the last hundred years. Really great progress has been made, but, despite the advances, we are still only at the threshold of the knowledge of many of the cerebral functions.

We use the term "localization" in somewhat different ways. Thus, we think of localization of function, we think of localization of lesions in certain diseases, and, again, we think of localization from the clinical standpoint of determining the sites of lesions.

The spadework in this domain was done by the anatomists, who taught us the topography of the surface of the brain, later, the histologists worked out the great fiber tracts within the brain.

On the lateral surface of the brain, the central sulcus separates the frontal from the parietal lobe, the fissure of Sylvius separates both from the temporal lobe. The motor area includes the anterior central gyrus and the feet

of the frontal gyrus. Broca's area for motor aphasia lies in the operculum, at the posterior part of the third left frontal gyrus. The somesthetic area lies mainly in the posterior central gyrus. The primary auditory center lies in the posterior part of the first temporal gyrus and in the transverse temporal gyri, with Wernicke's area for sensory aphasia (word-deafness) just below it. The *gyrus angularis* is an area important for reading and writing, since lesions there may cause alexia and agraphia.

On the medial surface, we remember that the lobulus paracentralis is an important motor area for the lower extremity, that the region of the calcarine fissure is concerned in vision, a unilateral lesion causing cortical hemianopsia, and that the uncus has to do with the perception of taste and smell. Tactile agnosia is usually associated with lesions of the middle third of the two central gyri, auditory agnosia with bilateral lesions of the superior temporal gyri and optic agnosia with lesions of the lateral parts of the occipital lobes. Lesions that cause apraxia may be either cortical or subcortical.

Meynert did a great service when he developed the idea of projection fibers as contrasted with association fibers. He showed us how certain long fiber tracts run from the cortex downward and others from below upward to the

Abstract of remarks made at the General Session of the American College of Physicians, Baltimore, March 24, 1931. Illustrated by lantern slides.

cortex and that they are massed together in the posterior limb of the internal capsule, the descending motor projection fibers in the anterior two-thirds of this posterior limb and the ascending sensory projection fibers in the posterior third. Thus, from before backward in the internal capsule we have the motor fibers for the face, head, arm and leg and, behind them in turn, the fibers for sensation. The projection fibers radiate from and to the cortex through the corona radiata.

During the last ten years, great progress has been made in the analysis of the functions of the fibers that extend between the corpus striatum and the midbrain, pons, medulla and spinal cord. No small part of this analysis has depended upon work done in connection with epidemic encephalitis and its sequels.

Surgeons who explored the brain in the search for tumors were able to localize with great accuracy certain points whence particular movements of, for instance, a thumb, or a single finger, can be elicited by electrical stimulation.

The projection fiber studies of Meynert were corroborated and greatly extended by the embryological researches of Flechsig of Leipzig, who showed us that the projection fiber tracts within the brain become myelinated long before the association tracts do. By suitable staining, the sequence of the myelination of the fibers can be determined. Thus, the fibers from the motor area of the anterior central gyrus and those to the sensory area of the posterior central gyrus, together with the visual fibers to the occipital lobe and the fibers for taste and smell to the uncus, are among the earliest to become myelinated.

Following upon these careful studies of the grosser structure of the brain came a series of minute microscopic examinations of the different parts of the cerebral cortex. Anyone who studies modern histological sections of the cerebral cortex cannot avoid being astounded by the complexity of organization in each single area. Thus, in a section from the anterior central gyrus, the motor area, one sees at least seven different layers of pyramidal cells of different sizes and arrangement.

Systematic examinations of the whole cerebral cortex from the standpoint of histological makeup have been made and it is possible to divide the cortex into a host of areas corresponding to the different histological pictures presented, though we are very far as yet from recognizing the functional significance of the differences.

Very careful studies have been made, too, of the blood supply of the human cerebral cortex. Personally, I was greatly surprised when I found how close the meshwork of capillaries is, and how different the arrangement of the capillaries is in different parts. You need only examine corrosion specimens after injection of the arterioles and capillaries in the cortex, magnified about 100 times, to realize the complexity. You can see the main arterioles and how they break up into the small meshes of smaller arterioles. On still further magnification of these small vessels, one wonders how there can be room between them for the nerve cells and the nerve fibers! The variations in the density of this meshwork of vessels probably has something to do with the distribution of poisons and of bacteria that are, in certain diseases, distributed to the brain. It, to some ex-

tent, determines the localization of poisons and of bacteria that enter the brain through the blood vessels

Careful studies have been made by Hugo Spatz at the Institute for Brain Research in Munich of the distribution of the lesions of epidemic encephalitis. Though the lesions may be widely disseminated, the distribution is largely in the white matter and in the basal ganglia. This can be no accident, something must determine the localization of the lesions due to the virus in this disease. One factor in the localization may lie in the character of the virus itself, a second factor, in all probability, lies in the blood vascular supply, and a third in varying local disposition of nerve-cells and fibers to the action of the virus or its toxins.

One sees great differences in the localization of the lesions in different varieties of encephalitis and this may be illustrated by reference to the distribution in diffuse periaxial encephalitis, in pyogenic encephalitis, in tuberculous meningo-encephalitis, in the cerebral form of epidemic encephalitis, and in the encephalomyelitic form. You will note that in epidemic encephalitis the basal ganglia are particularly prone to be involved in the neighborhood of the third ventricle and the aqueduct.

In recent years, the contributions of surgeons to cerebral localization through the exploration for tumors and other lesions have been vastly supplemented by the method devised by Dr. W. E. Dandy, who injected air into the ventricles or the subarachnoid space and made ventriculograms and encephalomyelograms by x-rays in both lateral and anterior views. By studying the distortions of the lateral ventri-

cle due to pressure, it is often possible to determine the exact position of tumors or cysts, that have not given definite localizing symptoms, and to remove them. The elimination of such space-occupying masses is, in some cases, just as important for differential diagnosis as the discovery of their presence in other cases. One cannot fail to recognize quickly the importance of this method for the diagnosis of hydrocephalus in its various forms and of brain tumors, cysts, and abscesses.

Last month, I was asked to study a girl of 15 who had epilepsy that was supposed to be of the idiopathic type, the attacks having persisted for several years. We made, however, a general neurological examination in the hope of finding symptoms or signs pointing to a focal lesion. In the course of the study, Dr. Angus L. MacLean made a most careful examination of the visual fields and discovered a beginning hemianopsia that involved the color fields more than the ordinary light fields, this pointed to a lesion of the optic pathway somewhere between the chiasm and the visual area in the occipital lobe. This gave the clue that the lesion was in the right half of the skull, probably behind its middle. I asked Dr. Dandy to see her and to decide whether or not to operate after making an air injection.

The arrangement was made with the parents that, if anything should be found during the air injection that warranted operation, they would permit it to be done at once. Dr. Dandy made a small opening in the skull put in a needle and suddenly felt it enter something soft. The air injection was then made and the roentgenograms.

immediately developed, revealed a cyst shown in the lateral view of the skull as in the posterior part of the right side of the brain

An antero-posterior roentgenogram showed that this cyst was of the size of a small orange. The needle had entered the cyst, but had not gone into the ventricle and the cyst did not communicate with the ventricle. Operation was proceeded with at once and the cyst was easily removed. The patient made a quick post-operative recovery and left the hospital at the end of three weeks. She was still having epileptic seizures, but though they may continue for a time, it is probable that they will disappear entirely later on, at any rate, in several similar cases they have done so. That was an interesting example of the possibilities of Dandy's encephalographic method of diagnosis.

The studies of brain tumor and of epilepsy have permitted a charting of the brain surface now that is much more complete than was ever before possible. Our clinical diagnosis of the situation of brain lesions has been greatly facilitated by such studies. The results of actual clinicopathological experience have been far more illuminating than all speculations regarding cerebral localization upon *a priori* grounds.

The psychologists have, in a praiseworthy way, tried to help out clinicians, but they have often been too visionary. You will recall that they have made a whole series of diagrams illustrating their conceptions of how brain centers must be connected with one another, and where the association paths between them must lie. These diagramatists went much too far; most of their

parallelograms and triangles presented in the textbooks are misleading. We must admit that, at present, the whole question of aphasia is still far from being satisfactorily answered. Though the brain area we are taught to look upon as the site of lesions that cause sensory aphasia is sometimes involved, there are a great many so-called "negative" cases and there are many bizarre cases that are difficult of explanation.

Some light seems recently to have been thrown upon cerebral localization by workers in comparative neurology and in experimental physiology. In *Science*, you will find a review by Karl S. Lashley* of the new work upon mass action in cerebral function, with particular reference to the difference between localized function and decentralized function in the brain. Though each part of the brain has its own particular function to serve, it also plays a part, it seems, in mass action, in the dynamic action of the brain surface as a whole.

If you remove a piece of cerebral cortex, you may abolish a certain function that belongs to that particular area, but you also influence certain other nervous functions at a distance, and that second influence appears to depend directly, no matter what part of the brain surface you excise, upon the amount of material that you remove from the cortex. It looks, therefore, as though there were some kind of "dynamic action of the brain surface as a whole", first upon other centers in the brain surface itself and, perhaps still more important, upon the subcortical centers. For example, it is said that the

*Lashley, K. C. Mass action in cerebral function. *Sci.* 1931, lxxiii, 245-254.

powers of a rat to learn and to retain what is learned can be greatly influenced by removal of any portion of the brain and that the influence exerted will be in exact correspondence to the amount removed. Learning and retention, in other words, what we call "intelligence", seems to be closely related to mass functions of the cortex.

It may, however, be found that what these comparative neurologists and psychologists are calling "mass function" may be group functions of areas associatively connected throughout this great cortex. We must wait and see. When I think of the immense network of fibers and the millions of nerve cells in the widely distributed cortex, I can-

not help but keep in mind the possibility that many areas probably act together and not in a wholly indifferent way. Multiple groups of cells and multiple groups of association fibers, working together, might easily influence other areas of the cortex and subcortical areas along with them.

The advances thus far made in the study of cerebral localization will certainly be a great stimulus to further study. During the next decade or two we shall, I believe, see remarkable advances in the further localization of function within the brain and they will undoubtedly add to our powers of precise clinical diagnosis.

THE SEVENTEENTH ANNUAL CLINICAL SESSION

The program for the Annual Meeting of the American College of Physicians, which will be held in Montreal during the week of February 6, 1933, is nearing completion. The meeting will take place at the height of Montreal's winter season. Those who attended the Minneapolis meeting will remember how well these northern cities are prepared for cold weather. With well heated buildings and taxicabs, the comfort of the guests is assured, and those who come from sections of the country possessing mild climates need have no hesitancy on account of the cold.

The General Meetings will be held in the Windsor Hotel, which is the headquarters and the Clinics will be concentrated in a few of the many hospitals of the city. The local Committee on Arrangements is making every effort to insure a meeting of highest excellence.

The General Program, following up the symposium on visceral neurology, which was so well presented and so enthusiastically received at the San Francisco meeting, will go still further into the physiologic aspects of medicine. There will be several papers dealing with the chemical and physical constitution, and their relationship to health and diseases. In a symposium on endocrinology the hormones from the pituitary, adrenal cortex, ovary and testis, parathyroid and pancreas will be discussed by men who engaged in the research work which resulted in their

discovery. The relationship of the vegetative nervous system to disease in general, will be stressed and the influence of the emotions in altering physiologic reactions will be emphasized. The program will thus stress pathologic physiology, the most alluring field of medical study today, and the field which must be thoroughly explored before we can understand how disease affects the individual. These studies emphasize the fact that "there is a patient who has the disease as well as a disease that has the patient."

Neurology and pediatrics, which have been somewhat neglected in recent programs, will be represented by several papers. Diseases of the heart and blood vessels, which are of such great interest to physicians, both in their practice and from a personal standpoint, will be presented from many angles. Diseases of the chest, including tuberculous and nontuberculous affections, will receive due attention. The latest work on pernicious anemia will be presented along with several other papers on diseases of the blood. There will be a discussion of the rôle of desensitization in the recovery from infectious diseases, and many papers dealing with subjects of general interest to internists.

The Clinical Program will be of the highest standard, presenting many problems of research and demonstrating the high type of clinical teaching for which Montreal is so well known.

(FRANCIS M. PORTER, M.D.,
President American College of Physicians.)

GASTRIC PHYSIOLOGY AND CLINICAL MEDICINE

In recent years medical literature has been rich with reports of studies of the gastric secretion, dealing with the physiological as well as with the clinical viewpoint. These studies have not been confined to the diseases of the stomach but have included many diseases in which the stomach had not been recognized previously as playing such an important part. The diagnostic survey of any severe anemia of obscure nature has come to demand a study of the gastric juice. In any chronic gall bladder or intestinal disorder the secretory and motor response of the stomach has become of interest in the light of newer observations. These researches serve as excellent examples of the correlated application of physiology, chemistry and clinical medicine, indeed, such correlation has been in a large measure responsible for many of the accomplishments of modern clinical investigation.

Symptoms, especially in chronic disease, are expressions of disturbed function. The gastro-intestinal tract is responsive in the production of symptoms in many types of disease, the lesion may be in the gastro-intestinal tract itself or it may be located quite remotely to the segment of the gastro-intestinal tract portraying the symptom. Often there is not any organic lesion demonstrable, the gastro-intestinal symptoms are merely somatic manifestations of a nervous system under emotional stress and strain, a poorly balanced or particularly responsive nervous system. In some patients the nervous system may receive and broadcast the faintest possible stimulus, it may be as poorly equipped to give an enjoyable program of life as

the radio that can not tune out the undesirable broadcast. The clinician must be alert and skillful, and frequently he must use the utmost ingenuity to differentiate the purely functional condition from the organic disease which may be manifest by the same symptom complex. Investigations of physiologic function should light the path to a more comprehensive understanding of such clinical problems.

The study of gastric secretion has enjoyed periods of popularity and enthusiasm for its use in diagnosis. Through the publications of the last few years one can sense the tendency to interpret function rather than to diagnosis, by gastric analyses. The advent of histamine into clinical use brought forth new methods and revival of the old methods with critical comparison of the value of each. It has been shown beyond a doubt that histamine is a powerful stimulant of hydrochloric acid secretion by the gastric mucosa. The method of Bloomfield and Pollard¹ has provided gastric juice as nearly in the original state of its secretion as it is possible to obtain (barring swallowing of saliva, gastric retention, or duodenal regurgitation). The extensive work of Bloomfield and his associates, and of many others, has demonstrated what may be expected of the gastric mucosa under the influence of histamine injected subcutaneously. Many publications have contributed a vast accumulation of figures. Up to the present time it has been very difficult to arrive at any definite conclusions on how to use this information clinically. The range of normal seems to be so great that one does not know where pathologic response begins. By some histamine has been considered the most powerful gastric stimulant for fact

acidity Evidence against this is available in the work of Comfort and Osterberg² in which they say "histamine failed to cause a secretion of free hydrochloric acid in one case in which the Ewald meal did cause such secretion, it produced secretion of free hydrochloric acid of a concentration less than that evoked by the Ewald meal in two other cases, and it produced concentration only equal to or within ten points of that evoked by the Ewald stimulus in fourteen cases"

If a fairly uniform response to a given dose of histamine in the same individual at different times could be demonstrated, the method of Bloomfield and Pollard would offer some possibility of a quantitative determination of hydrochloric acid excretion inasmuch as practically all of the secretion over a given period of time is obtained by continuous aspiration This would provide a functional test which could be used in an effort to get some measurable observation in the follow up of chronic gastric cases As yet there is insufficient evidence to show that there is always a constancy of response of volume and of hydrochloric acid secretion to a given amount of histamine in the same individual

Best³ and his associates have found histamine in considerable quantity in many organs the greatest amounts being in the liver, lungs and gastrointestinal tract Ivy⁴ and his co-workers have isolated histamine in crystalline form from the pyloric mucosa of the hog The presence of histamine in so many fresh normal tissues has suggested the possibility of its being of physiologic importance, but the presence of much more than a lethal dose of histamine in the body points to

strated an inactivating substance which they called histaminase⁵ It is interesting that histamine was not found in the gastric mucosa while a large amount was found in the mucosa of the small and large intestines The fate of histamine in the body is a question of great interest and possibly of considerable physiologic importance

With these recent contributions concerning the gastric physiology we have much information that we do not as yet know how to use, therefore we should be cautious in any dogmatic application in clinical medicine More doubt has been thrown on the diagnostic value of a single gastric analysis by any method, but, also it is demonstrated that in certain instances a single gastric analysis may furnish extremely valuable information when forming a link in the diagnostic chain More adequate quantities of human gastric juice are now available for the study of its known and unknown constituents and information is being provided for the more comprehensive understanding of the relationship of the stomach to the body as a whole

Analysis of 104 Cases of Carcinoma of the Large Intestine By HOWARD T KARSNER, M D, and BURTON CLARK, JR, M D (Am Jr Cancer, 1932, xvi, 933-970)

In this paper are reported the results of an analysis of 104 cases of proved carcinoma of the large intestine admitted to Lakeside Hospital, Cleveland, in the ten years ending in 1931. Maximum incidence of carcinoma of the colon is found to occur in the fifth and sixth decades of life and to be slightly earlier than for cancer of the rectum. Carcinoma of the colon is distinctly more common in males than in females. Anatomically, cancer is slightly more frequent in the rectum than in the colon. Of cancers of the colon, about one-third are in the sigmoid flexure, one-third in the proximal colon up to and including the hepatic flexure, and the other third in the transverse colon, splenic flexure and descending colon. Widespread metastasis is infrequent. Adenomatous polyps frequently become malignant. Pain is a frequent initial symptom, more especially of cancers of the rectum and sigmoid, but common in the course of the disease in all parts of the colon. Constipation is more notable with cancers of the left half of the colon than with those of the right, but is particularly common with cancers of the three flexures and ascending colon. Vomiting is often recorded with cancers of the splenic and hepatic flexures. Diarrhea is most frequent with the rectal cancers, and the same is true of the alternation of diarrhea and constipation. Blood in the stools is common with rectal cancers and decreases in frequency the higher the site of the cancer in the colon. Obstruction is observed particularly with cancers of the splenic flexure and is next most common with those of the hepatic flexure. Anemia is likely to be more severe in patients with cancer of the right half of the large intestine than in those with the disease

in the left half. Loss of weight is frequent and apparently is more common with cancers of the hepatic flexure, transverse colon, and splenic flexure.

Experimental Transmission of Tularemia by Mosquitoes By CORNELIUS B PHILIP, GORDON E DAVIS, and R R PARKER (Public Health Reports, 1932, xlvii, 2077-2088)

Several cases of human infection with *Bacterium tularensis* are on record in which there has seemed to be good reason to consider mosquitoes as possible vectors. Eight species of mosquitoes were used in a series of experimental investigations of the validity of this assumption. Mechanical transmission was shown to be possible, infection being transferred from infected to healthy guinea pigs by interrupted feeding of *Aedes aegypti* in one instance, and twice by crushing single specimens on the unbroken skin of guinea pigs, 24 hours and 9 days, respectively, after the original infecting feeding by the mosquitoes. Viable organisms were recovered from killed, and also from dead, incarcerated *Theobaldia* incensis up to the full life limit of the lot tested, and four days after death. Excrement of *Aedes triseriatus* pressed 24 hours after infecting blood-meals, and of *A. aegypti* 3 and 4 days after such meals was found to be infective. Thus it appears that mosquitoes which had fed on an animal infected with tularemia might infect persons mechanically (1) by biting after having been interrupted during their meal on the infected animal, (2) by being crushed on the skin with or without subsequent rubbing, and (3) by deposition of excrement on the skin. However, it is likely that suitable conditions to effect such transfers in nature are rare and it is probable that only minute infection of man would occur in this manner.

Retrobulbarneuritis durch Apiolvergiftung
[*Retrobulbar Neuritis in the Course of*
"*Apiol*" *Poisoning*] By DR ALEXANDER
JUHÁSZ-SCHÄFFER (Klin Wochenschr,
1932, xi, 1232)

Through reports from Holland, Germany, and Yugoslavia [also South America Editor] a new form of poisoning, "Apiol" poisoning, has been made known. There is a great similarity in the clinical course of the reported cases. Weakness and pain in the extremities, particularly the lower, are followed by varying degrees of paralysis of the involved region. The motor portions of the peripheral nerves are selectively affected. The lack of sensory changes is a point of differential significance in ruling out other forms of polyneuritis. To the case forming the basis of this report special interest attaches since in this patient there developed an acute unilateral retrobulbar neuritis with exophthalmos and limitation of adduction. "Apiol" has a wide reputation among the laity in Europe as an effective and readily obtained abortifacient and it is usually for this purpose that it has been taken in the cases in which poisoning has resulted. Toxic effects apparently depend upon the triorthocresyl phosphate present. [Note identity in clinical course and etiological agent with "jake" poisoning in this country. Editor.] The sale of "Apiol" should be restricted or prohibited.

Is the Increase of Cancer Real or Apparent?

By MARGR THURLOW MACKLIN, M.D.
(The Am Jr of Cancer, 1932, xvi, 1193-1205)

"Cancer is increasing, and it is increasing particularly in the age group over sixty. The reason for its increase is not that it is occurring at progressively younger ages, or attacking larger percentages of the younger population. Despite its increase, deaths are fewer from all causes than they were. We have withdrawn from the ravages of infectious disease; we have lost to those diseases which are dependent upon inherent qualities in the chemical and physical makeup of the individual. Cancer is increasing because of progress in medical treatment; there has been increase in longevity, better nutrition and

having grown old, they are kept from dying of those ills from which they formerly suffered. With each increase in the warfare against preventable diseases, there will be an increase in the ravages from cancer, for with each victory is created a greater available population to die from that disease.

"These conclusions are based upon the statistics of Canada. There is strong ground for believing that a similar analysis of the statistics of any other country would lead to the same conclusions. It is true that there may be racial differences in immunity to cancer, but the conclusion here reached will probably prove universal, namely, that excellent public health measures and high cancer rates are inseparable, at least for the present. Those who point to the low cancer rates existing among primitive peoples, and who state that cancer is a disease of modern civilization, neglect to call attention to the fact that preventive medicine is itself a triumph of modern civilization."

The Experimental Intravenous Administration of Colloidal Thorium Dioxide
By DUDLEY A. IRWIN, M.B. (Canada Med Assoc Jr, 1932, xxvii, 130-135)

A 25 per cent colloidal solution of thorium dioxide ("Thorotrast") when injected intravenously into rabbits was found to circulate for about five minutes in the colloidal state and then to flocculate. The flocculated particles were engulfed, for the most part, by the reticulo-endothelium of the liver, spleen, other lymphoid tissues, and bone marrow, and by parenchymatous cells of the liver. Thus fixed in a finely divided state, the thorium dioxide in the liver and spleen produced a shadow permitting the visualization of these organs. The shadow cast by bone marrow was obscured by the covering bone. With large doses the lymphatic glands could be visualized. The presence of thorium dioxide was innocuous in the tissues and no untoward reactions were observed following doses up to 5 cc per kilogram, during a period of four months. During this period there was no evidence of the elimination of the stored thorium dioxide from the spleen, bone marrow, or lymph nodes. In the liver, however, the thorium dioxide gradually ac-

cumulated in the Kupffer cells, which were believed to form emboli in the pulmonary capillaries, thus permitting this portion of the thorium compound to be eliminated in the bronchial mucus

Renal Glycosuria By ALEXANDER MARBLE, M.D. (Am Jr Med Sci, 1932, cxxxiii, 811-831)

Certain standards are set up which constitute a definition of "typical" renal glycosuria. Glycosuria without hyperglycemia must be present and sugar should be found in every specimen of urine examined, whether voided after fasting or after a full meal. The fasting blood sugar value (venous) should not reach nor exceed 0.12 gm per 100 cc, nor after a meal should the value reach or exceed

0.17 gm per 100 cc. Glycosuria should be largely independent of diet and the level of blood sugar should be influenced only slightly by the ingestion of food. The symptomatology characteristic of diabetes mellitus should be absent. The sugar found in the urine should be proved to be dextrose. No progression toward diabetes mellitus should be evident during at least three years of observation. A critical analysis of 9,000 consecutive cases of glycosuria revealed only 15 which met the above tests and which could therefore be considered true examples of renal glycosuria. No evidence of nephritis was found in any of these 15 patients. A history of glycosuria in relatives was obtained in 11. Because of the great rarity of renal glycosuria, care should be taken in making a final diagnosis of this disease.

Reviews

Man and Medicine: An Introduction to Medical Knowledge By DR. HENRY E. SIGERIST, Professor at the University of Leipzig. Introduction by DR. WILLIAM H. WELCH, Professor of the History of Medicine, The Johns Hopkins University. Translated by MARGARET GALT BOISE. + 340 pages. 1932. W. W. Norton & Company, Inc., New York. Price, \$4.00.

This English version of Sigerist's "Einführung in die Medizin" appears at a most appropriate time, for it has been announced that its distinguished author, who formerly succeeded Sudhoff in Leipzig, has accepted the chair of the history of medicine in The Johns Hopkins University upon the retirement of Dr. Welch. This book presents the history of medicine with a new breadth of vision and by a new method. Under seven major divisions—Man, Sick Man, The Signs of Disease, Disease, Causes of Disease, Medical Aid, and The Physician—is presented all of that mass of intimate knowledge which every man intrinsically craves in respect to the relationship between the human organism and disease processes. This book is

for the physician, it is also for the intelligent layman, and most of all is it for the medical student in the early days of his course. For him it is an experience in orientation in his chosen field. Throughout, the exposition of the knowledge of the present is enriched by abundant references to the past. Dr. Welch writes in the foreword:

"So simple, straightforward and devoid of unnecessary technicalities is the manner of exposition, that interest cannot fail to be aroused by the survey presented in this book of the relation to medical practice of existing knowledge of the structure and functions of the human body in health and in disease, of mental process, of epochal discoveries, of advancement of knowledge by observation and experiment of doctrines held at different times of the origin and nature of disease, of the attitude of society in different ages and countries toward the sick man, of the ideals of the physician and their relation to existing social and cultural conditions in different countries and periods, of the influence of religion and of sports upon the development of hygiene and of the

position of medicine in relation to the life and work of the individual and of society"

The Failing Heart of Middle Life By ALBERT S. HYMAN, A.B., M.D., F.A.C.P., Cardiologist, Beth David and Manhattan General Hospitals, Attending Physician and Cardiologist, Hospital for the Aged, Consulting Cardiologist, Harlem Day Nursery, Chief Cardiac Clinics, Beth David and Manhattan General Dispensaries, Director, Witkin Foundation for the Study and Prevention of Heart Disease, New York, N. Y., and AARON E. PARSONNET, M.D., C.M., F.A.C.P., Attending Physician and Cardiologist, Newark Beth Israel Hospital, Medical Director Home for the Aged, Fellow, Witkin Foundation for the Study and Prevention of Heart Disease, Newark, N. J., with a Preface by DAVID RIESMAN, M.D., Sc.D., F.A.C.P., Professor of Clinical Medicine, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania. xx + 538 pages, 160 illustrations and 4 plates. F. A. Davis Company, Philadelphia, 1932. Price, \$5.00 net.

The body of this book is divided into six parts, each containing a number of chapters pertaining to its subject matter. Part I deals with the coronary arterial system in health and disease. There is first a brief summary of the blood supply of the heart and then a discussion of the histological structure of the coronary arteries and of the physiologic changes through which they pass. This leads to the subject of coronary sclerosis with its clinical and pathological aspects. The final chapters deal with the various inflammatory lesions of the coronary arteries and the causes and effects of coronary thrombosis. Part II bears the title "The Myocardial Syndrome" and begins with a discussion of the lesions of the heart muscle which may properly be termed myocarditis. This leads to the conditions which the authors prefer to call myocardial infarction to true myocardial infarction. During the course of the book the complete mechanism of the myocardial infarction is described. Part III

is concerned with coronary thrombosis and occlusion. The symptoms of acute coronary thrombosis are described in detail and the important points in differential diagnosis are brought out. Special chapters are devoted to shock and blood pressure changes in this disease. Other chapters deal with the sequelae of coronary thrombosis and the accompanying physical signs. The discussion is then brought to a close by chapters on prognosis and treatment. In Part IV there is given a detailed description of the electrocardiographic findings in the various stages of degenerative heart disease. Over eighty well-chosen electrocardiograms are given to supplement and make clear the text. Part V deals with angina pectoris, discussing the mechanism of the pain production, the cardiac nerve supply and the symptoms of the anginal syndrome. Various theories of etiology are given as are also the immediate and secondary predisposing factors, including the effects of tobacco, alcohol and coffee. The relation of angina pectoris to associated disease conditions and the points of differentiation from coronary thrombosis are emphasized. Finally an excellent presentation of the treatment of this disease, including such recent advances as surgical procedures and the use of tissue extracts, is given. Part VI is devoted to the medicolegal aspects of sudden death from heart disease and in a clear, concise manner cites appropriate cases to illustrate the points made. This is a well written and interesting book which covers the subject adequately. Numerous brief case histories are included and these add to interest and clarity. At the end there is a bibliography of 1250 references rendering complete a work which will be particularly helpful to the general practitioner who has found it difficult to keep up with recent advances in cardiology.

B. M. H.

Diseases of the Kidney By W. GIBLING, BARR, F.R.C.S. (Eng.), Surgeon to St. Bartholomew's Hospital, London, and GEORGE L. LANS, M.D. (Cantab.), F.R.C.P. (Lond.), Physician with Charge of Out Patients, St. Bartholomew's Hospital, London. 424 pages, 8 colored plates, 152

text-figures P Blakiston's Son & Co, Inc, Philadelphia, 1932 Price, \$7.50

Girling and Ball have endeavored to give an account of kidney disease from the viewpoints of a physician and of a surgeon working in close collaboration. The field to be covered is therefore very broad and herein lies the value of this book. It presents the whole clinical area of pathological conditions of the kidney within a single cover. The first three chapters are devoted to the embryology, anatomy and physiology of the kidney, to a general review of the signs and symptoms of kidney disease and to the technic of examination. Then the various groups of renal lesions are considered. Bright's disease seems to have been put all too severely "in its place" for it, including amyloid disease, is granted but some 74 of the total of over 400 pages. Here the old terminology is followed except for the addition of a section on nephrosis. To many American readers this terminology will be highly confusing. For instance, Acute Interstitial Nephritis is found to refer to the kidney lesions of pyemia with multiple visceral abscesses, while in this country this term is generally accepted as designating the diffuse intertubular inflammatory process typified by postscarlatinal nephritis. This is the least satisfactory section of the book. On the whole, it is clear-cut and accurate in its statements, and the typography and illustrations are excellent. Many of the latter are from gross specimens in the Museum of St Bartholomew's Hospital and are very well chosen. This book can be recommended especially for its presentation of those renal conditions which are of surgical as well as medical import.

The Heart Rate By ERNEST P. BOAS, M.D., Associate Physician, Mt Sinai Hospital, New York City, and ERNST F. GOLDSCHMIDT, Ph.D., Research Fellow (1930-31), Department of Surgery in the Yale University School of Medicine. xi + 166 pages, 68 illustrations, numerous tables. Charles C. Thomas, Springfield, Illinois, and Baltimore, Maryland, 1932. Price, \$3.50 postpaid.

In this monograph are presented the data collected during a study of the heart rate by

means of the cardiograph, an electromagnetic device activated by the action currents of the heart. The studies concern healthy subjects under conditions of average activities, patients during anesthesia and operation, and patients under observation for cardiac disability. To the physician accustomed to place considerable weight on the pulse rate, it must come as something of a shock to learn how widely the healthy pulse rate varies under normal conditions even aside from the well known changes of rate induced by physical and emotional stimuli. Valuable clinical information is afforded by the author's studies on subjects during sleep and during anesthesia. The uniform reduction in rate during sleep offers a therapeutic approach in the management of various cardiac disabilities. The acceleration noted during unskillfully administered anesthetics should be unexpected only to the thoughtless. The absence of a significant correlation between body habitus and cardiac rate is surprising. The value of this observation is lessened somewhat by the fact that the morphologic constitutional type was determined by subjective judgment rather than actual measurement. This information would have been more valuable had the individual ages been tabulated in each group. The experiments are evidently carefully conducted and the results are recorded with an eye to detail. This monograph is well written and carries with it a useful and extensive bibliography. It should be available to every worker interested in the fields of cardiology and of metabolism.

H. G.

Practical Treatment of Skin Diseases with Special Reference to Technique By EDWARD AHLSSWIDE, M.D., formerly Assistant Physician, University Skin Department, Direction of Prof. Unna, Lippendorf Hospital, Hamburg, Assistant Physician, Clinic and Research Laboratory, Direction of Prof. Unna, Hamburg, Assistant Physician, Institute of Physical Therapy, Direction of O. Ahlswede, M.D., Hamburg. xxvi + 770 pages, 77 illustrations. Paul B. Hoeber, Inc., New York, 1932. Price, \$12.00.

This work differs from all others in the

field of dermatology. It is primarily and almost exclusively concerned with therapy. It not only states clearly what can and should be done for lesions of the skin, but also gives a concise presentation of the technical procedures involved. Naturally, the practices of the Unna school are most fully represented, but there seems to be a fair consideration of the work of others as well. In almost all instances, a sound understanding of the underlying pathology is evident in the brief characterizations of the various affections. However, mycosis fungoides is said to be of unknown etiology and there is no suggestion of the view so generally held in this country that it is a neoplasm of the lymphoblastoma group. Any disappointment felt in this regard is more than offset, however, by the italicized statement that pigmented nevi are best removed surgically with complete excision out of the healthy surrounding tissues and that local treatment of these growths should be avoided, particularly caustics, carbon dioxide snow, and irradiation. To this emphatic pronouncement from a dermatologist, pathologists will give their full approval. This work, with its highly practical arrangement, should prove to be of very great value.

Recent Advances in Pathology. By GEOFFREY HADFIELD, M.D., F.R.C.P. (Lond.), Professor of Pathology in the University of London, Pathologist to the Royal Free Hospital, and LAWRENCE P. GARRON, M.A., M.B., B.Ch. (Camb.), F.R.C.P. (Lond.) Bacteriologist and Lecturer in Bacteriology, Late Demonstrator of Pathology, St. Bartholomew's Hospital. x + 392 pages, 67 illustrations. P. Blakiston's Son & Co., Inc., Philadelphia, 1932. Price, \$3.50 net.

This is a worthwhile member of the Recent Advances Series. While many forward-looking investigations are not mentioned and could not have received extensive treatment, many in general the topics presented have been thoroughly and carefully dealt with.

Neoplasia as might be expected. The Reticulo-Endothelial System has its chapter, and two are devoted to the Cardio-Vascular System and two to Bright's Disease. The discussion of advances in knowledge of neoplasms is especially well written, while certain other chapters suffer by comparison. The section on Primary Cancer of the Lung is already out-of-date by from three to five years, and the same may be said of the subject matter dealing with the thyroid. The isolation of thyroxin in 1915 is scarcely a 'recent advance', nor should the work of Marine and Manby in 1916 be referred to as a recent study. Nevertheless, this book will prove a useful aid to those whose major textbooks in pathology do not include Asbestosis, Nephrosis, and Oligodendroglioma.

La Distomatosis Hepatica en Cuba [Hepatic Distomatosis in Cuba] By DR PEDRO KOURI and DR ROGELIO ARENAS. 175 pages, numerous illustrations, 1932. Distributed by the authors, Neptuno 115, Havana, Cuba.

This monograph is made up of reprinted articles from "Vida Nueva" with certain added material. The first section gives a detailed account of two human cases of hepatic distomatosis produced by *Fasciola hepatica*. In the second the occurrence of this condition in Cuba is surveyed and treatment is discussed, while in the third the specific action of emetine is emphasized.

Methodenlehre der therapeutischen Untersuchung [Methodology in Therapeutic Investigation] Von PAUL MARTINI, Professor der Medizin, Direktor der medizinischen Klinik der Universität Bonn. 69 pages, 9 illustrations. Verlag von Julius Springer, Berlin, 1932. Price, in paper, RM \$1.50.

This monograph presents a philosophical introduction to the theory of therapeutic investigation. Emphasis is placed upon mathematical analysis of apparent results in treatment and their evaluation.

College News Notes

The plan of assembling a library of all books published by members of the American College of Physicians was initiated about four years ago. Although much progress has been made through the receipt of gifts of books from members, there are a number of members who have not yet contributed books of which they are authors. This library will have a growing interest and value as years go by, for it is intended to be a memorial of our members.

The most recent contribution to the library has been made by Dr. John H. Musser (Fellow), New Orleans, La., editor of a new book entitled "Internal Medicine—Its Theory and Practice", published by Lea & Febiger, Philadelphia (1932). The book contains 1316 pages, consisting of twenty-seven chapters—each chapter contributed by a different individual, holding a professorial appointment in a medical school and selected because of particular interest in, and knowledge of, the subject of which he has written. Among the twenty-seven authors appear the following physicians who are Fellows of the American College of Physicians:

David P. Barr, St. Louis
 Arthur L. Bloomfield, San Francisco
 George E. Brown, Rochester, Minn.
 Robert A. Cooke, New York
 Charles F. Craig, New Orleans
 Ralph A. Kinsella, St. Louis
 Edward B. Krumbhaar, Philadelphia
 Isaac Ivan Lemann, New Orleans
 William Sharp McCann, Rochester, N. Y.
 James H. Means, Boston
 James Alex. Miller, New York
 John H. Musser, New Orleans
 O. H. Perry Pepper, Philadelphia
 Maurice C. Pineoffs, Baltimore
 Fred M. Smith, Iowa City
 Edward A. Strecker, Philadelphia
 Cyrus C. Sturgis, Ann Arbor
 Virgil Preston Sindensticker, Augusta
 Robert Grant Torrey, Philadelphia

Robert Van Valzah, Madison, Wis.

The following additional physicians, not Fellows of the College, are also contributors:

Marion Arthur Blankenhorn, Cleveland
 Alan M. Chesney, Baltimore
 Ernest Carroll Faust, New Orleans
 A. Graeme Mitchell, Cincinnati
 Hobart A. Reimann, Minneapolis
 Russell M. Wilder, Rochester, Minn.
 George Wilson, Philadelphia

President F. M. Pottenger has appointed the following standing Committee on ANNALS OF INTERNAL MEDICINE to have advisory supervision of the Journal:

Dr. James H. Means, Boston
 Dr. O. H. Perry Pepper, Philadelphia
 Dr. David P. Barr, St. Louis
 Ex-officio

The Editor

Acknowledgment is made of the following gifts to the College Library of publications by members:

Dr. Frederick R. Barnes (Fellow), Fall River, Mass.—2 reprints.

Dr. Archie A. Barron (Fellow), Charlotte, N. C.—1 reprint.

Dr. Moses Barron (Fellow), Minneapolis, Minn.—21 reprints.

Dr. Wm. R. Brookshier, Jr. (Fellow), Fort Smith, Ark.—7 reprints.

Dr. Harold C. Denman (Fellow), Brooklyn, N. Y.—1 reprint.

Dr. John A. Hooke (Associate), Detroit, Mich.—1 reprint.

Dr. George L. Steck (Fellow), Springfield, Mass.—1 reprint.

Dr. Martin J. Sennott (Fellow), Montclair, N. J.—1 reprint.

Dr. Pauline Williams (Fellow), Richmond, Va.—1 reprint.

Dr. Philip Worl (Fellow), Denver, Colo.—7 reprints.

Dr Albert F. R. Andresen (Fellow), Brooklyn, Dr. Henry L. Bockus (Fellow), Philadelphia, and Dr George B. Eusterman (Fellow), Rochester, Minn., are Vice-Chairman, Secretary and member of the Executive Committee, respectively, of the Section on Gastro-enterology and Proctology of the American Medical Association

Dr William S. Hubbard (Fellow), Chief of the Medical Service, St John's Hospital, Brooklyn, has retired (age limit) to the emeritus rank

Dr Irving Gray (Fellow), Brooklyn, is Chairman of the Scientific Section of the Second District Branch of the New York State Medical Society

Dr J. Burns Amberson (Fellow), New York City, attended the International Union Meeting at The Hague during September

Dr Henry C. Sweany (Fellow), Chicago, has been elected President of the Mississippi Valley Sanatorium Association

Dr Ernest S. Mariette (Fellow), Oak Terrace Minn., has been elected President of the Mississippi Valley Conference on Tuberculosis

Dr Gerald B. Webb (Fellow), Colorado Springs, has been named President-Elect of the Colorado State Medical Society

Under the Presidency of Dr L. J. Mooradian (Fellow), Oklahoma City, the Southern Medical Association held its annual meeting in Birmingham, Ala., November 16 to 18

The sixty-ninth session of the Homeopathic Medical Society of the State of Pennsylvania was held at Sky Top Lodge, Monroe County, Pa., September 27, 28 and 29. The following members participated as members:

Dr Carl V. Vrener (Fellow), Philadelphia, President of the Bureau of Homeopathic Medicine.

Dr H. J. P. Fennell (Fellow), Philadelphia, presented a paper on "The Application

of an Isopathic Treatment to a Case of Sulpharsphenamine Poisoning as recommended by Richter",

Dr E. Roland Snader, Jr (Fellow), Philadelphia, presented a paper on "Unusual Laboratory Findings in Diabetes Mellitus",

Dr Ralph Bernstein (Fellow), Philadelphia, presented a paper on "Dermatologic Aphorisms",

Dr Carl V. Vischer (Fellow) and Dr Lowell L. Lane (Associate), both of Philadelphia, presented a paper on "A Clinical Consideration of the Paroxysmal Tachycardias",

Dr G. Harlan Wells (Fellow), Philadelphia, discussed a paper by Dr Clarence Bartlett, "Fallacies and Traditions in Medicine",

Dr Dunne W. Kirby (Associate), Philadelphia, discussed the paper mentioned above by Dr Ferguson,

Dr Grant O. Favorite (Associate), Philadelphia, presented a paper on "Infectious Mononucleosis—Case Report",

Dr Samuel W. Sappington (Fellow) and Dr Grant O. Favorite (Associate), both of Philadelphia, had charge of the Scientific Exhibits A—Heart Pathology, B—Tumors of the Large Intestine,

Dr William Devitt (Fellow), Allenwood, Pa., was the guest speaker of the Bureau of Clinical Medicine

Dr Frank N. Allan (Fellow), who has been Associate in Medicine at the Mayo Clinic, Rochester, Minn., and Instructor in Medicine at the University of Minnesota (Mayo Foundation), has resigned to accept a position with the Lahey Clinic, Boston, Mass.

Dr Egerton Crispin (Fellow), Los Angeles, Calif., President of the Resident and Ex-Resident's Association of the Mayo Clinic and the Mayo Foundation, delivered the presidential address at the annual meeting, October 13, 14 and 15, at Rochester, Minn., on "Changing Forces in Medicine".

Dr William C. Mooradian (Fellow), St. Paul, Minn., addressed the annual meeting of the National Health Officer Association

at San Diego, September 26 on "Trends in the Control of Tuberculosis", and on October 11 spoke before the monthly meeting of the Santa Cruz Medical Society on "Pulmonary Conditions Wrongly Diagnosed as Tuberculosis"

Dr E J G Beardslev (Fellow), Philadelphia, addressed "The Porch Club" of Riverton, N J, October 4, on "The Search for Health and Happiness as a Physician Views It"

Dr Beardslev was a guest speaker of the West Jersey Homeopathic Medical Society at its meeting at the Tavestock Country Club, Haddonfield, N J, October 14, his subject being "Complete Routine Physical Examinations vs Intuitive Diagnoses"

The Inter-State Postgraduate Medical Association of North America held its annual Assembly at Indianapolis October 24-28, under the Presidency of Dr Arthur D Bevan, of Chicago. The following Fellows of the College contributed to the program as indicated

Dr O H Perry Pepper, Philadelphia—Diagnostic Clinic and "Comments on the Group of Diseases Attributed to Filterable Viruses",

Dr Elsworth S Smith, St Louis—Diagnostic Clinic and "Prognosis and Treatment of Ambulatory Cases Presenting the Angioid Syndrome",

Dr David P Barr, St Louis—Diagnostic Clinic and "The Effects of Diseases of the Thyroid Gland on the Heart",

Dr Lewellys F Barker, Baltimore Md—Diagnostic Clinic and "The Scenic Patient";

Dr Warfield T Longcope, Baltimore—Diagnostic Clinic and "Constipation"

Dr Cyrus C Sturgis, Ann Arbor, Mich—Diagnostic Clinic and "Pernicious Anemia",

Dr W McKim Marriott, St Louis—Diagnostic Clinic (Pediatrics) and "Polio-myelitis",

Dr Charles A Elliott, Chicago—Diagnostic Clinic and "The Leukemias—Their Significance and Their Treatment",

Dr Emanuel Libman, New York City—

Diagnostic Clinic and "Immediate and Ultimate Prognosis in Cardiac Disease",

Dr Henry A Christian, Boston—Diagnostic Clinic and "Pharmacological Action of Digitalis",

Dr Elliott P Joslin, Boston—Diagnostic Clinic and "The Present Status of the Diabetic Child",

Dr Harlow Brooks, New York City—Diagnostic Clinic and "Essential Hypertension—Its Implications and Treatment"

Dr Willis F Manges (Fellow) Philadelphia, delivered an address on "The Development of Roentgenology", at the opening of Jefferson Medical College of Philadelphia on September 21

Dr Ross V Patterson (Fellow), dean of the Jefferson Medical College, announced the appointments to the staff of Dr Henry K Mohler (Fellow), Philadelphia, and Dr Harold W Jones (Fellow), Philadelphia as Associate Professors of Medicine

Dr Frieda Baumann (Fellow), Philadelphia, has been promoted to Associate Professor of Applied Therapeutics in the Woman's Medical College of Pennsylvania

Dr W H Stoner (Fellow), formerly Medical Director of Hoffmann-La Roche Inc Nutley N J is now attached as Research Consultant to the Experimental Research Laboratories of Burroughs Wellcome & Company, at Tuckahoe N Y. He will visit institutions in the United States and Canada in which research of medical significance is conducted, and will then publish a report of the survey for the aid of research workers in avoiding duplication of effort, and in establishing contacts between workers in similar fields

Dr Salvatore Torricone (Fellow) Marquette, Mich, has been elected President of the Michigan Sanatorium Association

Dr Samuel Goldberg (Associate), Philadelphia has been appointed to the staff of the Department of Pediatrics of Temple

University School of Medicine A sixty-bed addition to the building of the Department has been begun

Dr Edward Weiss (Fellow), Philadelphia, has been appointed as Clinical Professor of Medicine, and Dr Joseph C Doane (Fellow), Philadelphia, has been promoted to Clinical Professor of Medicine in the Department of Medicine at the above institution

Dr Clyde Brooks (Fellow), formerly Professor of Physiology and Pharmacology at the University of Alabama School of Medicine, has been appointed to the staff of

the Louisiana State University Medical Center, New Orleans, as Professor of Physiology

Dr Augustus Warren Crane (Fellow), Kalamazoo, Mich, was the recipient of the honorary degree of Master of Arts from the University of Michigan on the occasion of its 83rd Annual Founder's Day Ceremony at the Medical School on September 26 The address by Dr Crane on that occasion dealt with development of knowledge of magnetic and electrical phenomena leading up to the work of Roentgen

OBITUARIES

DOCTOR RAY CARRINGTON BLANKINSHIP

Dr Ray Carrington Blankinship (Fellow), Madison, Wisconsin, died suddenly of coronary thrombosis at Huntington, West Virginia, August 23, 1932

Dr Blankinship was born at Brookneal, Virginia, July 31, 1890 He obtained his undergraduate education at Virginia Polytechnic Institute and his medical education at the Medical College of Virginia, at which institution he received the degree of Doctor of Medicine in 1914 He served an eighteen months' internship at Kings County Hospital, Brooklyn, N. Y. and then returned to Virginia to practice medicine at Marion. In December of 1917 he was commissioned a lieutenant in the Medical Corps of the United States Army and was sent to Camp Travis, San Antonio, Texas, where he remained until March, 1919

In 1917 he married Eleanor Adelaide Stone of Stoughton, Wisconsin and

upon leaving the Army, he returned to civil practice at Stoughton From there he moved to Madison to join the staff of the University of Wisconsin Student Health Service He later specialized in gastro-intestinal diseases, and upon the establishment of the four year course in medicine at the University of Wisconsin in 1925, he became chief of the division of gastro-enterology, as Associate Professor of Clinical Medicine This position he held at the time of his death

Dr Blankinship was a member of the Wisconsin State Medical Association, a Fellow of the American Medical Association, and had been a Fellow of the American College of Physicians since 1922

The following is quoted as a part of a resolution adopted by the faculty of the University of Wisconsin Medical School:

"The rare characteristics of humanist and scientist combined in him the best of the old family doctor and the new scientific physician He knew both

the art and science of medicine His interest in people made him acutely sensitive to that relation of physician to patient which cannot be reached by science His patients, recognizing in him the artful practice of scientific medicine, were obedient to his orders and became his life long friends "

(Furnished by J S EVANS, M D , F A C P , Madison, Wis)

DOCTOR LUTHER C DAVIS

Dr Luther C Davis was born in Fairmont, West Virginia, 1894, where he made his preliminary preparation for medicine He was matriculated in the University of Wisconsin, and later entered the University of Missouri where he took his A B degree in 1916 His first intention was to be a chemist but he changed to be a physician, entering the University of Pennsylvania where he was awarded his M D degree, 1920 He served an internship and returned to Fairmont to practice
